Abstract

Tissue factor pathway inhibitor (TFPI) is a plasma Kunitz-type serine protease inhibitor that directly inhibits coagulation Factor Xa and also inhibits tissue factor-initiated coagulation. Normal human plasma TFPI exists both as the full-length molecule and as variably carboxy-terminal truncated forms. We reported recently that the low density lipoprotein receptor-related protein mediates the cellular degradation of TFPI after TFPI binding to the hepatoma cell surface. To examine whether the carboxy terminus of TFPI was required for interacting with hepatoma cells, a mutant of TFPI lacking the third Kunitz-type domain and basic carboxy terminus was generated. We found that this mutant, TFPI-160, did not compete with full-length ¹²⁵I-TFPI-160 for binding to hepatoma cells. We were also unable to demonstrate specific binding of ¹²⁵I-TFPI-160 to hepatoma cells at 4°C. At 37°C, significantly less ¹²⁵I-TFPI-160 was internalized and degraded via low density lipoprotein receptor-related protein than full-length ¹²⁵I-TFPI. Full-length ¹²⁵I-TFPI binding to hepatoma cells could be inhibited > 90% by heparin and other highly charged molecules. Since TFPI, but not TFPI-160, was capable of effectively binding to cultured hepatoma cells, the fates of TFPI and TFPI-160 in vivo were examined. Both ¹²⁵I-TFPI and ¹²⁵I-TFPI-160 disappeared rapidly from the circulation after their intravenous administration into rats. The initial plasma half-life of ¹²⁵I-TFPI was ~ 30 s whereas the half-life of ¹²⁵I-TFPI-160 was ~ 4 min. ¹²⁵I-TFPI was cleared predominantly by the liver. In contrast, ¹²⁵I-TFPI-160 accumulated in the outer cortex of the kidney. Using microscopic autoradiography, we demonstrate that ¹²⁵I-TFPI clearance is largely hepatocellular, whereas ¹²⁵I-TFPI-160 accumulates mainly in the cells of the kidney proximal tubules. Together our findings demonstrate that the carboxy-terminal region(s) distal to amino acid 160 of TFPI mediates TFPI binding to hepatoma cells both in vitro and in vivo. (*J. Clin. Invest.* 1995; 95:1773–

1781.) **Key words:** tissue factor pathway inhibitor • binding • clearance • carboxy terminus

Introduction

Tissue factor pathway inhibitor (TFPI)¹ is a trace ~ 40-kD plasma glycoprotein (~ 2.0 nM) that plays a key role in the regulation of tissue factor (TF)-initiated blood coagulation (1, 2). TFPI was initially identified after the observation that preincubation of TF with serum prevented the lethal disseminated intravascular coagulation that occurs after TF infusion in animals (3, 4). This observation suggested there was an inhibitor of TF in serum. This serum inhibitor, currently called TFPI, was subsequently purified from various sources including human hepatoma HepG2 cells (5, 6), plasma lipoproteins (7), and postheparin plasma (8). The cDNA was cloned from human placental and fetal liver cDNA libraries (9). Mature TFPI, 276 residues, contains an acidic amino-terminal domain followed by three tandem Kunitz-type protease inhibitory domains, and a basic carboxy-terminal domain (9).

TFPI regulates coagulation via its abilities to directly inhibit coagulation Factor Xa and to inhibit the Factor VIIa-TF complex of the extrinsic pathway of blood coagulation (10). The extrinsic pathway of coagulation is initiated when damage to blood vessels at the site of a wound allows TF to gain access to the plasma. Plasma Factor VII or VIIa binds to TF and the Factor VIIa-TF complex proteolytically activates Factors IX and X, triggering a cascade of events which eventually leads to the generation of thrombin and the formation of a fibrin clot (1, 2). Inhibition of the Factor VIIa-TF complex by TFPI occurs in two steps. In the first step, Factor Xa binds to the second Kunitz-type domain of TFPI, and in the second step, the TFPI-Factor Xa complex binds to the TF-Factor VIIa complex through an interaction between the first Kunitz-type domain and Factor VIIa, forming a Factor Xa-TFPI-Factor VIIa-TF complex (11). The function of the third Kunitz-type domain is not known.

The majority of circulating TFPI is not in the form of the full-length molecule but is truncated at various positions in its carboxy terminus (12). The enzyme(s) responsible for carboxy-terminal truncation has not been identified and whether proteolysis modulates TFPI activity in vivo is also not known. Using a carboxy-terminal truncated variant of TFPI lacking the third Kunitz-type domain and basic carboxy terminus (TFPI¹⁻¹⁶¹), Hamamoto et al. (13) reported that TFPI¹⁻¹⁶¹ inhibited cell surface Factor VIIa-TF proteolytic activity towards Factor X identically to full-length TFPI. Carboxy-terminal truncated TFPI and full-length TFPI have also been shown to inhibit Factor Xa and Factor VIIa-TF equally in endpoint-type assays (14). However, carboxy-terminal truncated TFPI possesses considerably less anticoagulant activity as measured in one stage coagulation assays because full-length TFPI is a more potent inhibitor of the prothrombinase complex (14–16).

Volume 95, April 1995, 1773–1781

After the intravenous administration of TFPI into rabbits, TFPI is rapidly cleared from the circulation (initial $t_{1/2}$ of ~ 2 min) and accumulates in the liver and kidney (17, 18). Bregengaard et al. (18) reported that the carboxy terminus of TFPI was important in mediating rapid TFPI clearance because 2 min after intravenous injection the recovery in plasma of TFPI¹⁻¹⁶¹ was ~ 15 -fold higher than full-length TFPI. Heparin, which binds to the basic carboxy terminus of TFPI and to a portion of the third Kunitz-type domain (14, 15), was found to reduce the clearance of full-length TFPI ~ 10 - 15 -fold but had no effect on the clearance of TFPI¹⁻¹⁶¹ (18).

Using hepatoma cell lines, we reported recently (19) that the low density lipoprotein receptor-related protein (LRP) mediates TFPI degradation. The cellular degradation of ¹²⁵I-TFPI was inhibited $> 80\%$ by both antibodies directed against LRP and by the LRP-associated 39-kD protein, a protein that copurifies with LRP and inhibits all known ligand interactions with LRP. LRP, however, does not appear to be the major cell surface receptor for TFPI since ¹²⁵I-TFPI binding at 4°C is not inhibited by the 39-kD protein. We proposed that after TFPI binds to the hepatoma cell surface, LRP mediates the cellular degradation of TFPI. The purpose of this study was to examine the importance of the carboxy terminus of TFPI in interacting with the hepatoma cell surface TFPI receptor and/or LRP both in vitro and in vivo.

Methods

Materials. Iodogen was purchased from Pierce Chemical Co. (Rockford, IL). Enzymobeads were from Bio-Rad Labs. (Richmond, CA). Carrier-free sodium [¹²⁵I]iodide and Hyperfilm-MP were purchased from Amersham Corp. (Arlington Heights, IL). Sprague-Dawley rats were obtained from Harlan Sprague Dawley, Inc. (Indianapolis, IN). Pronase, bovine serum albumin (fraction V), and low molecular weight heparin (#375097) were from Calbiochem-Novabiochem (La Jolla, CA). Heparin (#H9768), heparan sulfate (#H7641), dextran sulfate (#D4911), pentosan polysulfate (#P8275), chondroitin sulfate (#C2413), and poly L lysine with mean molecular weights of 1-4 kD (#P0879) and 15-30 kD (#P7890) were from Sigma Immunochemicals (St. Louis, MO). Tissue culture medium was from GIBCO BRL (Gaithersburg, MD). Protein A-agarose was from Repligen Corp. (Cambridge, MA). Kodak NTB-2 and Kodak D19 developer were from Eastman Kodak Co. (Rochester, NY).

Proteins. Recombinant human full-length TFPI (containing the basic carboxy terminus) was a gift from the Monsanto Co. (Chesterfield, MO). A cDNA encoding a truncated form of TFPI (TFPI-160) was constructed in which the codon triplet for glycine 160 was followed by two consecutive TGA stop codons and an appropriate HindIII restriction site. This cDNA was inserted into the pMON6875 expression vector and the production of TFPI-160 in *Escherichia coli* was essentially as described for full-length TFPI except that the sample was reappplied to a Q Sepharose fast flow column (Pharmacia LKB Biotechnology Inc., Piscataway, NJ), pH 8.0, instead of a mono S column in the final purification step (20). After SDS-PAGE and staining with Coomassie brilliant blue, TFPI-160 migrates as a single band of 22 kD. α_2 -Macroglobulin was purified from human plasma and activated by incubation with methylamine (to yield α_2 M*) (21). The full-length rat 39-kD protein and constructs encoding residues 1-114 and 115-319 of the 39-kD protein were produced as fusion proteins with glutathione S-transferase (GST) in *E. coli*. The GST fusion proteins were purified by glutathione-agarose chromatography (21). The full-length GST 39-kD protein was cleaved with thrombin and free 39-kD protein was purified via heparin-agarose chromatography (21).

Antibodies. Polyclonal rabbit antibodies were generated against full-length human TFPI and total IgG was prepared using protein A-agarose (14).

Protein iodinations. TFPI and TFPI-160 (25 or 50 μ g) were iodinated using the Iodogen method (22). α_2 M* (20 μ g) was iodinated using Enzymobeads (22). Specific radioactivities were typically 0.5 - 4×10^7 cpm/ μ g protein.

Cell binding and degradation assays. Rat hepatoma MH₁C₁ cells were cultured as described previously (22). Cells were seeded into 12-well dishes 2 d before assay. Cell monolayers were used at 80-90% confluency. Assay buffer for TFPI and TFPI-160 was Earle's minimal essential medium (with glutamine) containing 3% (wt/vol) bovine serum albumin (BSA). Assay buffer for α_2 M* was Dulbecco's modified Eagle's medium containing 6 mg/ml BSA and 5 mM CaCl₂ (21). Cell monolayers were washed twice on ice with 0.5 ml of the appropriate prechilled assay buffer and binding was initiated by adding 0.35 ml of 4°C assay buffer containing the indicated concentrations of ¹²⁵I-labeled proteins in the absence or presence of unlabeled competitors. After incubation at 4°C for 2 h, buffer containing unbound ligand was removed and the cells were washed three times with 4°C PBS or assay buffer. The cells were then lysed in 62.5 mM Tris-HCl, pH 6.8, containing 0.2% (wt/vol) SDS and 10% (vol/vol) glycerol (low SDS-lysis buffer) and radioactivity of cell lysates was determined in a γ counter (model C5304; Packard Instruments, Meriden, CT). Nonspecific binding was determined in the presence of excess unlabeled ligand as specified in each figure.

Degradation assays were performed by washing cell monolayers twice with room temperature assay buffer. Then 0.35 ml of assay buffer containing the indicated concentrations of ¹²⁵I-labeled proteins in the absence or presence of unlabeled competitors was added for 4 h at 37°C. Thereafter, the overlying medium was removed and proteins were precipitated by the addition of BSA to 5 mg/ml and trichloroacetic acid to 10%. Degradation of ligand was defined as the appearance of radioactive ligand fragments in the overlying medium that were soluble in trichloroacetic acid. Degradation of ¹²⁵I-ligand in parallel dishes that did not contain cells has been subtracted from the total degradation. After removal of the overlying medium, the cell monolayers were washed three times with PBSc (PBS containing 1 mM CaCl₂ and 0.5 mM MgCl₂). Cells were then lysed in low SDS-lysis buffer and cell-associated radioactivity was quantified. Alternatively, cells were incubated for 30 min at 4°C with PBSc containing 0.25% (wt/vol) Pronase, which removes cell surface radioligand and also detaches cells from the culture wells. The detached cells were separated from the buffer by centrifugation. Radioactivity of the supernatant fractions (defining cell surface Pronase-sensitive radioligand) and radioactivity associated with the cell pellets (defining internalized Pronase-resistant radioligand) were determined separately. Cellular protein per well was determined using a Bio-Rad protein assay with BSA as a standard.

In vivo plasma clearance. Female Sprague-Dawley rats (weighing 200-220 g) were anesthetized with sodium pentobarbital (15 mg/200 g rat) during the time of the experiment. ¹²⁵I-TFPI or ¹²⁵I-TFPI-160, (6 - 8×10^6 cpm) in sterile 0.15 M NaCl (total volume 500 μ l), was injected into a tail vein over 30 s. Blood samples (50-100 μ l) (total volume < 800 μ l) were collected from the tail artery at the indicated times after injection into tubes containing 10 μ l of 0.5 M EDTA. Each of the blood samples was centrifuged, and 10-20 μ l of the plasma fractions was spotted onto 3-mm filter paper (Whatman Inc., Clifton, NJ), precipitated with 10% trichloroacetic acid, rinsed with ethanol, and ¹²⁵I-radioactivity was determined. The initial plasma concentrations (time = 0) of ¹²⁵I-TFPI and ¹²⁵I-TFPI-160 were obtained by extrapolating the amount of radioactivity from the first two (TFPI) or six (TFPI-160) measured samples. At the times specified in the text, the animals were killed and the liver, kidneys, and spleen were removed, blotted, weighed, and ¹²⁵I-radioactivity was determined.

Autoradiography. Samples of the kidneys and livers from rats injected with ¹²⁵I-TFPI or ¹²⁵I-TFPI-160 were fixed with 10% phosphate-buffered formalin and embedded in paraffin. Sections of embedded tissues were mounted on gelatin-coated slides, deparaffinized, rehydrated with water, and then air dried. Some slides were directly placed against Hyperfilm-MP for 40 d. Other slides were covered with a photographic emulsion (Kodak NTB-2) for the indicated periods of time before development with Kodak D19 developer diluted 1:1 with water. These slides

Figure 1. Effect of the 39-kD protein on the cellular degradation, cellular association, and internalization of ^{125}I -TFPI and ^{125}I -TFPI-160. Rat hepatoma MH_1C_1 cells were incubated with 2.5 nM ^{125}I -TFPI (\bullet) or 10 nM ^{125}I -TFPI-160 (\circ) in the absence or presence of increasing concentrations of the 39-kD protein for 4 h at 37°C . Thereafter the overlying medium was removed and proteins were subjected to trichloroacetic acid precipitation. The cell monolayers were then washed to remove unbound ligand and either directly lysed (with SDS) to determine cell-associated radioactivity or, alternatively, the cell monolayers were treated with Pronase. In A, trichloroacetic acid-soluble radioactivity, representing degraded radioligand is shown. B demonstrates cell-associated radioactivity after lysis of the cell monolayers with SDS. In C, cell surface (Pronase-sensitive) radioligand is indicated. D shows internalized (Pronase-resistant) radioligand. Radioactivity was converted to femtomole equivalents of ^{125}I -TFPI and ^{125}I -TFPI-160 calculated from the specific activities and is normalized per milligram of protein. Each symbol represents the average of duplicate determinations from two separate experiments.

were then stained with hematoxylin and eosin and examined microscopically to delineate grain distributions.

Immunoprecipitations. Plasma samples from the indicated time points of rats injected with ^{125}I -TFPI (25 μl) or ^{125}I -TFPI-160 (15 μl) or $\sim 100,000$ cpm of starting ^{125}I -TFPI and ^{125}I -TFPI-160 were mixed with PBS (final volume 500 μl) and immunoprecipitated with 10 μg of total anti-TFPI IgG/sample at 4°C for 4 h (TFPI samples) or overnight (TFPI-160 samples). 60 μl of a 50% slurry of protein A-agarose was added for 2 h at 4°C . Nonspecifically bound radioactivity was removed by washing the protein A-agarose beads three to four times with PBS containing 1% (vol/vol) Triton X-100, 0.5% (wt/vol) sodium deoxycholate, 1% (wt/vol) SDS, and 0.5% (wt/vol) BSA. The immunoprecipitated material was released from the beads by boiling each sample for 5 min in 62.5 mM Tris-HCl, pH 6.8, 2% (wt/vol) SDS, 10% (wt/vol) glycerol, and 5% (vol/vol) 2-mercaptoethanol (Laemmli sample buffer) (23). The entire plasma immunoprecipitates and $\sim 10,000$ cpm of the starting immunoprecipitates were subjected to 12.5% SDS-PAGE. The gels were fixed, dried, and exposed to film.

Results

Effect of the 39-kD protein on the cellular degradation and cellular association of ^{125}I -TFPI and ^{125}I -TFPI-160. We reported previously that LRP mediates the cellular degradation of ^{125}I -TFPI after ^{125}I -TFPI binding to the hepatoma cell surface (19). To examine whether the carboxy terminus of TFPI was important for interacting with hepatoma cells/LRP, a construct encoding amino acids 1-160 of TFPI was produced in *E. coli* and purified. This construct, TFPI-160, consists of the first two Kunitz-type domains of TFPI and lacks the third Kunitz-type domain and basic carboxy terminus. The ability of the 39-kD protein to alter LRP-mediated degradation of ^{125}I -TFPI-160 was examined by incubating rat hepatoma MH_1C_1 cells with 10 nM ^{125}I -TFPI-160 in the absence or presence of increasing concentrations of the 39-kD protein for 4 h at 37°C . As a control, 2.5

nM of full-length ^{125}I -TFPI was similarly incubated with MH_1C_1 cells. Thereafter, the medium overlying the cell monolayers was subjected to trichloroacetic acid precipitation, and trichloroacetic acid-soluble radioactivity, representing degraded ligand, was determined. As seen in Fig. 1 A and as demonstrated previously (19), the 39-kD protein inhibits the cellular degradation of ^{125}I -TFPI in a dose-dependent manner. The K_i value² for inhibition is ~ 70 nM. Degradation of ^{125}I -TFPI (initial concentration 2.5 nM) is reduced from 308 fmol/mg protein in the absence of the 39-kD protein to 65 fmol/mg protein in the presence of 1 μM 39-kD protein. The 39-kD protein also inhibits the cellular degradation of ^{125}I -TFPI-160 (initial concentration 10 nM) in a dose-dependent manner. Degradation is reduced from 89 fmol/mg protein in the absence of the 39-kD protein to 18 fmol/mg protein in the presence of 1 μM 39-kD protein.

We next examined whether the 39-kD protein alters the cellular association of ^{125}I -TFPI and ^{125}I -TFPI-160. After incubation at 37°C for 4 h, the overlying medium was removed and the cells were rinsed to remove unbound ligand. Cells were then lysed in a buffer containing 0.2% SDS, and radioactivity of the cell lysates was determined. Fig. 1 B demonstrates that the 39-kD protein has no effect on the cellular association of ^{125}I -TFPI. The cellular association of ^{125}I -TFPI-160 (initial concentration 10 nM), however, is reduced from 55 fmol/mg protein in the absence of the 39-kD protein to 17 fmol/mg protein in the presence of 1 μM 39-kD protein.

We reported previously that LRP is not the major receptor for TFPI on the hepatoma cell surface since the 39-kD protein did not inhibit ^{125}I -TFPI binding at 4°C (19). The inability of the 39-kD protein to inhibit the cellular association of ^{125}I -TFPI

2. K_i is defined as the concentration of competitor which inhibits 50% of radioligand binding or degradation.

at 37°C (Fig. 1 B) also suggests that the majority of TFPI is not associating with LRP. To examine whether the 39-kD protein was altering the intracellular association of ^{125}I -TFPI (and ^{125}I -TFPI-160) with LRP, cell monolayers were treated with Pronase after incubation for 4 h at 37°C. Pronase treatment digests cell surface radioligand, thereby separating surface (Pronase-sensitive) from internalized radioligand (Pronase-resistant) (24). As seen in Fig. 1 C, the 39-kD protein has no effect on cell surface-associated ^{125}I -TFPI but does inhibit, in a dose-dependent manner, ^{125}I -TFPI internalization (Fig. 1 D). Fig. 1 C also shows that the 39-kD protein inhibits the cell surface association of ^{125}I -TFPI-160 (initial concentration 10 nM) by ~ 50% (17 fmol/mg protein in the absence of the 39-kD protein vs 9 fmol/mg protein in the presence of 1 μM 39-kD protein). Internalization of ^{125}I -TFPI-160 (Fig. 1 D) is also inhibited by the 39-kD protein (38 fmol/mg protein in the absence of the 39-kD protein vs 9 fmol/mg protein in the presence of 1 μM 39-kD protein). Fig. 1, B and C, also demonstrates that in the absence of the 39-kD protein significantly less ^{125}I -TFPI-160 is associated with hepatoma cells than full-length ^{125}I -TFPI.

Inhibition of ^{125}I -TFPI-160 internalization by 39-kD protein constructs. To define whether the amino and/or carboxy terminus of the 39-kD protein is responsible for inhibiting ^{125}I -TFPI-160 internalization, MH₁C₁ cells were incubated for 4 h at 37°C with various concentrations of GST fusion proteins encoding residues 1–114 (GST/1–114) and residues 115–319 (GST/115–319) of the 39-kD protein. Thereafter, the overlying medium was removed and the cell monolayers were rinsed and treated with Pronase. Fig. 2 demonstrates that GST/115–319 inhibits ^{125}I -TFPI-160 internalization (Pronase-resistant) essentially identically to the full-length 39-kD protein with or without GST (GST/1–319 and 1–319, respectively). The K_i values for inhibition of internalization by GST/115–319, GST/1–319, and 1–319 are each ~ 200 nM. Internalization of ^{125}I -TFPI-160 (initial concentration 10 nM) is reduced from ~ 17 fmol/mg protein in the absence of the 39-kD protein vs ~ 4 fmol/mg protein in the presence of 1 μM GST/115–319, GST/1–319, and 1–319. The amino-terminal construct, GST/1–114, inhibits ^{125}I -TFPI-160 internalization poorly with a K_i value \geq 1,000 nM. GST alone does not alter ^{125}I -TFPI-160 internalization.

Effect of TFPI and TFPI-160 on the binding, cellular association, and cellular degradation of ^{125}I - $\alpha_2\text{M}^*$. We reported previously that TFPI inhibits the binding and degradation of ^{125}I - $\alpha_2\text{M}^*$ by MH₁C₁ cells.³ Therefore we compared the ability of TFPI with TFPI-160 to alter ^{125}I - $\alpha_2\text{M}^*$ binding at 4°C and to alter the cellular association/degradation of ^{125}I - $\alpha_2\text{M}^*$ at 37°C. Fig. 3 A demonstrates that TFPI inhibits ^{125}I - $\alpha_2\text{M}^*$ binding to MH₁C₁ cells essentially identically to the 39-kD protein (K_i values ~ 20 nM). ~ 85% of specific ^{125}I - $\alpha_2\text{M}^*$ binding is inhibited by the 39-kD protein (1 μM) and TFPI (1 μM). In contrast, TFPI-160 only slightly (~ 10%) inhibits ^{125}I - $\alpha_2\text{M}^*$ binding. TFPI and the 39-kD protein similarly inhibit the cellular association (Fig. 3 B) and cellular degradation of ^{125}I - $\alpha_2\text{M}^*$ (Fig. 3 C) at 37°C, whereas 1 μM TFPI-160 inhibits ~ 10% of ^{125}I - $\alpha_2\text{M}^*$ degradation.

Binding of ^{125}I -TFPI and ^{125}I -TFPI-160 to hepatoma cells. The above findings suggested that only a very small fraction of ^{125}I -TFPI-160 associated with the hepatoma cell surface and was

Figure 2. Inhibition of ^{125}I -TFPI-160 internalization by 39-kD protein constructs on rat hepatoma MH₁C₁ cells. Cells were incubated for 4 h at 37°C with 10 nM ^{125}I -TFPI-160 in the absence or presence of increasing concentrations of various 39-kD protein constructs. Thereafter, the buffers overlying the cell monolayers were removed and the cells were rinsed to remove unbound ligand. The cell monolayers were treated with Pronase, and Pronase-resistant (internalized) ^{125}I -TFPI-160 was determined. The constructs used were 1–319 (○), GST/1–319 (●), GST/1–114 (▲), GST/115–319 (■), and as a negative control, GST (◆). ^{125}I -TFPI-160 internalized in the absence of any 39-kD protein construct was defined as 100%. Each symbol represents the average of duplicate determinations from two separate experiments.

internalized and degraded via LRP. Therefore, we examined whether the third Kunitz-type domain and basic carboxy terminus of TFPI were required for binding to hepatoma cells. The ability of TFPI-160 to inhibit the binding of full-length ^{125}I -TFPI to MH₁C₁ cells and the ability of ^{125}I -TFPI-160 to directly bind to MH₁C₁ cells were examined. As seen in Fig. 4, unlabeled TFPI inhibits the binding of ^{125}I -TFPI (2.5 nM) with a K_i value of ~ 80 nM. Fig. 4 also shows that unlabeled TFPI-160, at concentrations ranging from 20 to 1,000 nM, does not effectively inhibit ^{125}I -TFPI binding. To examine whether ^{125}I -TFPI-160 bound specifically to MH₁C₁ cells, saturation binding experiments were performed over the concentration range of 5–50 nM. We found that TFPI-160 either did not bind specifically to MH₁C₁ cells or that the binding affinity was so low that no discernable K_d value could be obtained from the data (data not shown). Together these results demonstrate that carboxy-terminal residues 161–276 are required on TFPI for efficient binding to hepatoma cells.

Effect of heparin and other charged molecules on ^{125}I -TFPI binding. Since the basic carboxy terminus of TFPI and a portion of the third Kunitz-type domain have been shown previously to bind heparin (14, 15) and since this region is important for TFPI binding to hepatoma cells, the ability of heparin and other charged molecules to alter ^{125}I -TFPI binding to MH₁C₁ cells was examined. Fig. 5 demonstrates that these molecules inhibit ^{125}I -TFPI binding in a dose-dependent manner. The order of potency is: dextran sulfate ~ pentosan polysulfate > heparin

3. Warshawsky, I., J. Herz, G. J. Broze, Jr., and A. L. Schwartz, unpublished observations.

Figure 3. Effect of TFPI, TFPI-160, and the 39-kD protein on the binding, cellular association, and cellular degradation of $^{125}\text{I}-\alpha_2\text{M}^*$. In A, MH_1C_1 cells were incubated for 2 h at 4°C with 50 pM of $^{125}\text{I}-\alpha_2\text{M}^*$ in the absence or presence of increasing concentrations of unlabeled 39-kD protein (●), TFPI (■), or TFPI-160 (▲). 100% binding was determined in the absence of any competitors. Nonspecific binding (6% of total binding) was determined in the presence of 50 nM unlabeled $\alpha_2\text{M}^*$ and has been subtracted from each point. In B and C, MH_1C_1 cells were incubated for 4 h at 37°C with 50 pM of $^{125}\text{I}-\alpha_2\text{M}^*$ in the absence or presence of increasing concentrations of unlabeled 39-kD protein (●), TFPI (■), or TFPI-160 (▲). Thereafter, the overlying medium was removed and subjected to trichloroacetic acid precipitation. The cell monolayers were washed and cell-associated radioactivity was determined. Cell-associated (B) and degraded (trichloroacetic acid-soluble) (C) $^{125}\text{I}-\alpha_2\text{M}^*$ are indicated. $^{125}\text{I}-\alpha_2\text{M}^*$ cell-associated or degraded in the absence of any competitor was defined as 100%. Each symbol represents the average of duplicate determinations.

~ low molecular weight heparin > heparan sulfate ~ poly L-lysine (15–30 kD) > chondroitin sulfate ~ poly L-lysine (1–4 kD). Greater than 90% of ^{125}I -TFPI binding could be inhibited at the highest dose of competitor added.

Clearance of ^{125}I -TFPI and ^{125}I -TFPI-160 in the rat. Since TFPI, but not TFPI-160, was capable of effectively binding to

hepatoma cells *in vitro*, the fates of TFPI and TFPI-160 were examined *in vivo*. Approximately $6-8 \times 10^6$ cpm of ^{125}I -TFPI and ^{125}I -TFPI-160 was intravenously injected into the tail veins of rats. The disappearance of ^{125}I -radioactivity (trichloroacetic acid-precipitable) from rat plasma was followed over time. Fig. 6 A demonstrates that ^{125}I -TFPI disappears rapidly from the plasma with an initial half-life of ~ 30 s. Approximately 20% of the administered dose of ^{125}I -TFPI remained in the circulation between 1 and 10 min. At 10 min after intravenous

Figure 4. Binding of ^{125}I -TFPI to rat hepatoma MH_1C_1 cells in the absence or presence of unlabeled TFPI or TFPI-160. Cells were incubated for 2 h at 4°C with 2.5 nM ^{125}I -TFPI in the absence or presence of increasing concentrations of unlabeled TFPI (●) or unlabeled TFPI-160 (○). ^{125}I -TFPI bound in the absence of any competitor was defined as 100%. Each symbol represents the average of duplicate determinations from two separate experiments.

Figure 5. Effect of heparin and other charged molecules on ^{125}I -TFPI binding. MH_1C_1 cells were incubated for 2 h at 4°C with 2.5 nM ^{125}I -TFPI in the absence or presence of increasing concentrations of dextran sulfate (●), pentosan polysulfate (○), heparin (▲), low molecular weight heparin (Δ), heparan sulfate (■), poly L-lysine (15–30 kD) (□), chondroitin sulfate (◆), and poly L-lysine (1–4 kD) (◇). 100% binding was determined in the absence of any competitors. Each symbol represents the average of duplicate determinations from one to three separate experiments.

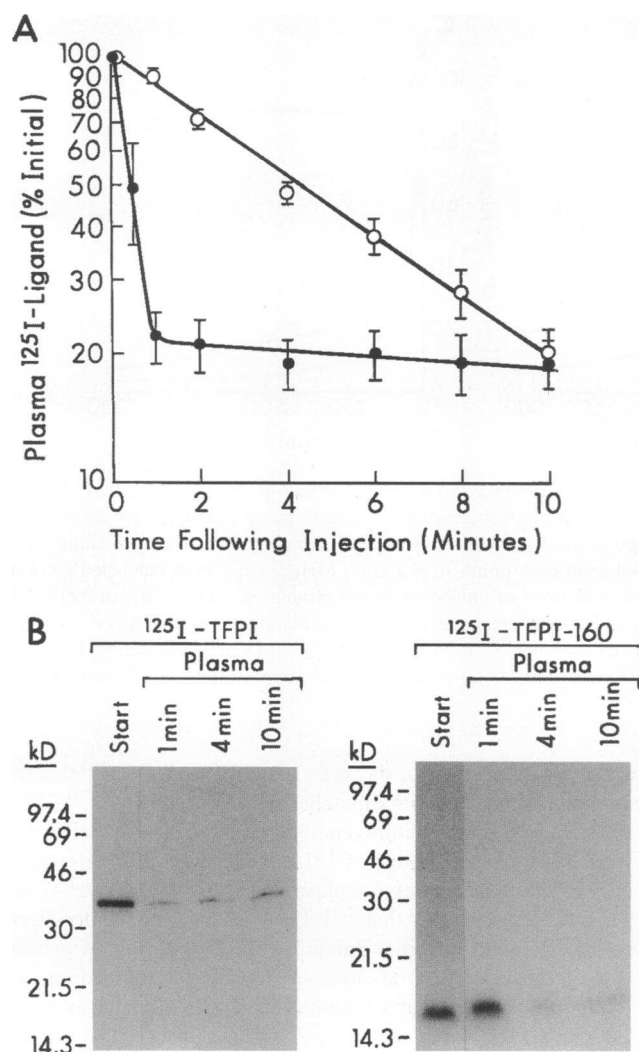

Figure 6. (A) Clearance of $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ in the rat. Rats were injected with $6-8 \times 10^6$ cpm of $^{125}\text{I-TFPI}$ (\bullet) ($n = 7$ rats) or $^{125}\text{I-TFPI-160}$ (\circ) ($n = 4$ rats). Blood samples were collected at the indicated times and trichloroacetic acid-insoluble radioactivity was determined. Each symbol represents the mean \pm SEM. (B) SDS-PAGE of plasma samples. Plasma samples collected 1, 4, and 10 min after intravenous administration of $^{125}\text{I-TFPI}$ (left) or $^{125}\text{I-TFPI-160}$ (right) were immunoprecipitated with anti-TFPI IgG. Immunoprecipitates of the plasma samples, as well as immunoprecipitates of the starting $^{125}\text{I-TFPI}$ or $^{125}\text{I-TFPI-160}$, were analyzed by 12.5% SDS-PAGE. Gels were exposed to film 3 d (TFPI samples), 20 h (start TFPI-160), or 4 d (TFPI-160 plasma samples) before developing. Molecular mass markers in kilodaltons are indicated.

injection, the percentages of $^{125}\text{I-TFPI}$ associating with the liver, kidneys, and spleen were 25, ~ 2 , and $< 1\%$ of the injected dose, respectively (Table I). Fig. 6 A also shows that $^{125}\text{I-TFPI-160}$ disappears rapidly from the circulation after intravenous administration. $^{125}\text{I-TFPI-160}$ clearance was linear over 10 min and the plasma half-life was ~ 4 min. At 10 min, $\sim 20\%$ of the injected dose remained in the circulation. The amount of $^{125}\text{I-TFPI-160}$ associating with the liver, kidneys, and spleen was determined 10 min ($n = 2$ rats), 15 min ($n = 1$ rat), and 35 min ($n = 1$ rat) after intravenous administration of $^{125}\text{I-TFPI-160}$. The organ distributions were similar at the three time points and were therefore averaged. As seen in Table I, and in

Table I. Tissue Distribution of ^{125}I -Radioactivity after Intravenous Injections of $^{125}\text{I-TFPI}$ or $^{125}\text{I-TFPI-160}$

$^{125}\text{I-Ligand}$	Percent ^{125}I -radioactivity/organ			n
	Liver	Kidney	Spleen	
TFPI	25 ± 3.2	2.4 ± 0.72	0.71 ± 0.12	7
TFPI-160	9.0 ± 0.87	77 ± 10.9	1.0 ± 0.07	4

Seven rats were injected with $6-8 \times 10^6$ cpm of $^{125}\text{I-TFPI}$. After 10 min, the animals were killed, organs were obtained, and their content of ^{125}I -radioactivity was determined. Four rats were injected with $6-8 \times 10^6$ cpm of $^{125}\text{I-TFPI-160}$. After 10 min ($n = 2$ rats), 15 min ($n = 1$ rat), or 35 min ($n = 1$ rat), the animals were killed and ^{125}I -radioactivity associating with the liver, kidneys, and spleen was determined. n , number of animals in each group. Data are expressed as mean \pm SEM.

marked contrast to the results with $^{125}\text{I-TFPI}$, 9, 77, and 1% of the injected $^{125}\text{I-TFPI-160}$ accumulated in the liver, kidneys, and spleen, respectively.

Plasma samples obtained 1, 4, and 10 min after the intravenous administration of $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ into rats were subjected to immunoprecipitation with anti-TFPI antibodies. After SDS-PAGE and autoradiography, both $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ were found to migrate identically to the starting ^{125}I -labeled proteins (Fig. 6 B). Fig. 6 B also shows that the disappearance of $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ over time on SDS-PAGE parallels the disappearance seen in Fig. 6 A. Furthermore, $^{125}\text{I-TFPI}$ could be immunoprecipitated from plasma samples obtained 1, 4, and 10 min after intravenous administration using a carboxy-terminal antipeptide rabbit antibody generated against amino acids 265-276 of TFPI (14) (data not shown). These results demonstrate that full-length TFPI is not being proteolyzed at the carboxy terminus for at least 10 min after its intravenous administration.

Sites of $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ clearance. Tissue sections of kidney and liver were prepared after the in vivo administration of $6-8 \times 10^6$ cpm of $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$. ^{125}I -Radioactivity localizes to the outer cortex of the kidney in rats injected with $^{125}\text{I-TFPI}$ (Fig. 7 A) and $^{125}\text{I-TFPI-160}$ (Fig. 7 B). The intensity of radioactivity is substantially greater in the kidneys of rats injected with $^{125}\text{I-TFPI-160}$ than in rats injected with $^{125}\text{I-TFPI}$. The patterns of radioactivity in the livers from rats injected with $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$ were homogeneous. The intensity of radioactivity was substantially greater in the livers of rats injected with $^{125}\text{I-TFPI}$ than in rats injected with $^{125}\text{I-TFPI-160}$. To examine which cell type(s) in the kidney and liver accumulated $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$, kidney and liver sections were prepared 10 min after their intravenous injections and examined by microscopic autoradiography. Fig. 8 A ($\times 300$, 3-wk exposure) is a hematoxylin and eosin-stained autoradiogram of a kidney section from a rat injected with $^{125}\text{I-TFPI}$. The grains localize both to the glomeruli and to the cells of the proximal tubules (predominantly on the apical surface). Autoradiograms of kidney sections from a rat administered $^{125}\text{I-TFPI-160}$ are seen in Fig. 8 B ($\times 300$, 2-d exposure), 8 C ($\times 200$, 3-wk exposure), and 8 D ($\times 100$, 3-wk exposure). As seen, the vast majority of the grains are located in cells of the proximal tubules and are largely on the apical surface. Only a very minor fraction of the grains is glomerular. Fig. 8, E and F ($\times 200$, 3-wk exposures), are autoradiograms of liver sections from rats injected with $^{125}\text{I-TFPI}$ and $^{125}\text{I-TFPI-160}$, respectively. The ma-

Figure 7. Autoradiograms of kidney and liver sections from rats injected with ^{125}I -TFPI or ^{125}I -TFPI-160. Rats were killed 10 min after intravenous administration of $6-8 \times 10^6$ cpm of ^{125}I -TFPI (A) or ^{125}I -TFPI-160 (B). The kidneys and liver were dissected out and fixed with formalin. Paraffin-embedded sections were prepared and exposed to film 40 d before developing.

majority of the grains is hepatocellular and neither ^{125}I -TFPI nor ^{125}I -TFPI-160 appears to significantly localize to the hepatic vascular endothelium. Significantly more grains are seen in the livers of rats injected with ^{125}I -TFPI than ^{125}I -TFPI-160.

Discussion

In this study, we have demonstrated that carboxy-terminal residues 161–276 of TFPI are required for its specific binding to hepatoma cells *in vitro* and *in vivo*. TFPI-160, which contains the first two Kunitz-type domains and lacks the third Kunitz-type domain and basic carboxy terminus, neither binds specifically to cultured hepatoma cells nor inhibits the binding of full-length ^{125}I -TFPI to hepatoma cells at concentrations ranging from 20 to 1,000 nM. In addition, TFPI-160 only has a slight effect on the binding and cellular degradation of ^{125}I - $\alpha_2\text{M}^*$ whereas TFPI completely inhibits each of these processes. Moreover, after intravenous administration of ^{125}I -TFPI and ^{125}I -TFPI-160 into rats, ^{125}I -TFPI accumulates predominantly in the liver, whereas ^{125}I -TFPI-160 accumulates in the outer cortex of the kidneys. The clearance curve we obtained after injection of tracer doses of full-length ^{125}I -TFPI into rats is similar to those described previously after bolus or tracer dose administration of TFPI into rabbits (17, 18, 25), baboons (26), and rats (27) in that the alpha phase of clearance is extremely rapid. The reported beta phase half-lives vary from 17 min to 2 h (17, 18, 26). The recoveries of TFPI in plasma between 10 min and 4 h after intravenous administration also vary (from ~ 3 to $\sim 40\%$) and may reflect differences in the TFPI preparations administered (17, 18, 25–27). We found that between 1 and 10 min, $\sim 20\%$ of the injected ^{125}I -TFPI was still remaining in the circulation (Fig. 6 A), and at 10 min, 25% was associated with the liver. It is not clear where the remaining 55% of injected ^{125}I -TFPI accumulates. Circumstantial evidence suggests that TFPI may be bound to heparan sulfate proteoglycans or glycosaminoglycans on the endothelial cell surface. This hypothesis is based on the observations that: (a) TFPI binds to heparin agarose (14); (b) heparin and sulfated polysaccharides enhance the anticoagulant activity of TFPI (28); and (c) after intravenous administration of heparin, plasma levels of TFPI increase severalfold (8, 29). Thus it is possible that the 55% of ^{125}I -TFPI is bound to the vascular endothelium in various tissues. The observation that the vast majority of ^{125}I -TFPI clearance was hepatocellular and not associated with the hepatic

vascular endothelium (Fig. 8 E), however, argues against ^{125}I -TFPI being bound to the vascular endothelium.

In sharp contrast to the hepatocellular accumulation of ^{125}I -TFPI, ^{125}I -TFPI-160 accumulated mainly in the cells of renal proximal tubules (Fig. 8, B–D). The small fraction of ^{125}I -TFPI that associated with the kidneys also localized to the proximal tubules as well as to the glomeruli (Fig. 8 A). The vastly different tissue distribution observed with TFPI and TFPI-160 suggests that the third Kunitz-type domain and/or carboxy terminus confers liver specificity. It is also possible that the acidic amino terminus and/or first two Kunitz-type domains confers kidney specificity. It is not clear whether TFPI and TFPI-160 are being filtered/reabsorbed. It is also not clear whether TFPI and TFPI-160 are binding specifically to a renal protein although a likely candidate would be glycoprotein 330 (gp330), a member of the LDL-receptor family that localizes to clathrin-coated pits of kidney proximal tubules and glomerular epithelium (30–32). It is interesting to note that $\alpha_2\text{M}^*$ does not bind to gp330 (33, 34), and that TFPI-160, which associates with the kidney after intravenous administration, only slightly alters the binding and cellular degradation of ^{125}I - $\alpha_2\text{M}^*$. The potential involvement of gp330 in the endocytic internalization of TFPI and TFPI-160 will be the subject of future studies.

We reported previously that, after TFPI binding to the hepatoma cell surface, LRP mediates the cellular degradation of TFPI since both antibodies directed against LRP as well as the full-length 39-kD protein or residues 115–319 of the 39-kD protein each inhibit $> 80\%$ of ^{125}I -TFPI degradation (19).³ In addition, we reported that LRP was not the major hepatic cell surface receptor for TFPI since ^{125}I -TFPI binding at 4°C was not inhibited by the 39-kD protein (19). In the current study, we found ^{125}I -TFPI internalization (Pronase-resistant) but not the total cellular association (i.e., cell surface plus internalized) or cell surface association (Pronase-sensitive) of ^{125}I -TFPI could be inhibited by the 39-kD protein. This is consistent with the notion that the majority of ^{125}I -TFPI is not binding to LRP but that TFPI uptake and degradation occurs via LRP.

Since TFPI-160, which lacks the basic heparin-binding carboxy terminus of TFPI, did not bind to hepatoma cells, we examined whether heparin and related negatively charged molecules altered ^{125}I -TFPI binding. We found that heparin, as well as other sulfated polysaccharides, inhibited ^{125}I -TFPI binding. However, it is not clear at present whether inhibition resulted from direct competition for the cell surface TFPI-binding pro-

Figure 8. Microscopic autoradiograms of kidney and liver sections from rats injected with ^{125}I -TFPI or ^{125}I -TFPI-160. Rats were intravenously injected with $6\text{--}8 \times 10^6$ cpm of ^{125}I -TFPI or ^{125}I -TFPI-160. After 10 min, the kidneys and livers were removed and paraffin-embedded sections were processed for autoradiography and stained with hematoxylin and eosin. (A) ^{125}I -TFPI, kidney, 3-wk exposure, $\times 300$. (B) ^{125}I -TFPI-160, kidney, 2-d exposure, $\times 300$. (C) ^{125}I -TFPI-160, kidney, 3-wk exposure, $\times 200$. (D) ^{125}I -TFPI-160, kidney, 3-wk exposure, $\times 100$. (E) ^{125}I -TFPI, liver, 3-wk exposure, $\times 200$. (F) ^{125}I -TFPI-160, liver, 3-wk exposure, $\times 200$.

tein or whether these molecules bound directly to TFPI (i.e., to the basic carboxy terminus), thereby preventing ^{125}I -TFPI from binding to the cell surface and yielding apparent inhibition of binding. These results may suggest that the primary TFPI-binding species on hepatoma cells is acidic. Inhibition of ^{125}I -TFPI binding by poly L-lysine may have resulted from poly L-lysine binding to the acidic TFPI-binding species on the hepatoma cell surface and thus preventing ^{125}I -TFPI from binding.

We reported previously that carboxy-terminal residues 115–319 of the 39-kD protein, generated as a fusion protein with GST, inhibit the cellular degradation of ^{125}I -TFPI essentially

identically to the full-length 39-kD protein, GST/1–319.³ Although the 4°C binding assays demonstrated that TFPI-160 did not interact with hepatoma cells to a substantial degree (Fig. 4), we examined whether TFPI-160 was capable of interacting with LRP by testing whether the 39-kD protein altered TFPI-160 degradation by cultured hepatoma cells. After incubation at 37°C , we found that the 39-kD protein inhibited the cellular association, internalization, and degradation of ^{125}I -TFPI-160 (Fig. 1, B–D). Similar to the results obtained with full-length TFPI, residues 115–319 of the 39-kD protein inhibited TFPI-160 internalization essentially identically to the full-length 39-

kD protein (Fig. 2). The relative amount of TFPI-160 internalized and degraded, however, was markedly less than that seen with full-length TFPI. This suggests that the third Kunitz-type domain and/or the basic carboxy terminus contains residues important for interaction with LRP. Alternatively, it is possible that TFPI may be optimally recognized by LRP only while bound to the primary TFPI-binding species.

Acknowledgments

We thank the Monsanto Company for generously providing the purified TFPI.
