Research Article

Propylthiouracil (PTU) in maximally inhibitory doses for liver and kidney iodothyronine 5'-deiodinase activity (5'D-I), reduces extrathyroidal T4 to T3 conversion by only 60-70% in euthyroid rats. A second pathway of T4 to T3 conversion (5'D-II) has been found in pituitary, central nervous system, and brown adipose tissue. 5'D-II is insensitive to PTU and increases in hypothyroidism, whereas 5'D-I decreases in hypothyroid rats. Thyroxine (T4) and triiodothyronine (T3) kinetics were assessed in euthyroid and thyroidectomized rats by noncompartmental analysis after injecting [125I]T4 and [131I]T3. Neither the volume of distribution nor the rate of fractional removal of plasma T4 was affected by the thyroid status, but the fractional removal rate of T3 was approximately 50% reduced in hypothyroid rats (P less than 0.001). Fractional T4 to T3 conversion was 22% in euthyroid and 26% in hypothyroid rats. In euthyroid rats, sufficient PTU to inhibit liver and kidney 5'D-I greater than 90% reduced serum [125I]T3 after [125I]T4 (results given as percent dose per milliliter $\times 10^{-3}$ \pm SEM): 4 h, control 16 \pm 2 vs. PTU 4 \pm 1, P less than 0.005, and 22 h, control 6.4 \pm 0.4 vs. PTU 3.6 \pm 0.7, P less than 0.025. Abstract. Propylthiouracil (PTU) in maximally inhibitory doses for liver and kidney iodothyronine 5'-deiodinase activity (5'D-I), reduces extrathyroidal T4 to T3 conversion by only 60–70% in euthyroid rats. A second pathway of T4 to T3 conversion (5'D-II) has been found in pituitary, central nervous system, and brown adipose tissue. 5'D-II is insensitive to PTU and increases in hypothyroidism, whereas 5'D-I decreases in hypothyroid rats. Thyroxine (T4) and triiodothyronine (T3) kinetics were assessed in euthyroid and thyroidectomized rats by non-compartmental analysis after injecting [¹²⁵I]T4 and [¹³¹I]T3. Neither the volume of distribution nor the rate of fractional removal of plasma T4 was affected by the thyroid status, but the fractional removal rate of T3 was ~50% reduced in hypothyroid rats ($P < 0.001$). Fractional T4 to T3 conversion was 22% in euthyroid and 26% in hypothyroid rats. In euthyroid rats, sufficient PTU to inhibit liver and kidney 5'D-I >90% reduced serum [¹²⁵I]T3 after [¹²⁵I]T4 (results given as percent dose per milliliter $\times 10^{-3} \pm \text{SEM}$): 4 h, control 16 ± 2 vs. PTU 4 ± 1 , $P < 0.005$, and 22 h, control 6.4 ± 0.4 vs. PTU 3.6 ± 0.7 , $P < 0.025$. In thyroidectomized rats, the same dose of PTU also inhibited 5'D-I in liver and kidney, but had no effect on the generation of serum [¹²⁵I]T3 from [¹²⁵I]T4. Similarly, after 1 μg T4/100 g bw was given to thyroidectomized rats, serum T3 (radioimmunoassay) increased

by 0.30 ± 0.6 ng/ml in controls and 0.31 ± 0.09 ng/ml in PTU-treated rats. However, when the dose of T4 was increased to 2–10 $\mu\text{g}/100$ g bw, PTU pretreatment significantly reduced the increment in serum T3. T3 clearance was not affected by PTU in hypothyroid rats. The 5'D-II in brain, pituitary, and brown adipose tissue was reduced to $\leq 60\%$ of control by 30 $\mu\text{g}/100$ g bw reverse T3 (rT3), an effect that lasted for at least 3 h after rT3 had been cleared. In rT3-pretreated thyroidectomized rats, the generation of [¹²⁵I]T3 from tracer [¹²⁵I]T4 was reduced in the serum: 6 ± 1 vs. $12 \pm 1 \times 10^{-3}\%$ dose/ml, $P < 0.01$, during this 3-h period.

We conclude that virtually all the T3 produced from low doses of exogenous T4 given to hypothyroid rats is generated via a PTU-insensitive pathway, presumably catalyzed by the 5'D-II. This is a consequence of the enhanced activity of this low K_m enzyme together with the concomitant decrease in the hepatic and renal 5'D-I characteristic of the hypothyroid state. The results indicate that in some circumstances, 5'D-II activity may contribute to the extracellular, as well as intracellular, T3 pool.

Introduction

In euthyroid man and rat, most of the serum triiodothyronine (T3)¹ is generated from 5'-deiodination of thyroxine (T4) (1–3). Given the comparatively high concentration of a membrane-bound iodothyronine-5'-deiodinase in liver and kidney, these tissues are considered to be the main source of extrathyroidally produced T3 (4–6). One of the characteristics of this enzyme is to be uncompetitively inhibited by propylthiouracil (PTU)

1. *Abbreviations used in this paper:* bw, body weight; BAT, brown adipose tissue; 5'D-I, liver and kidney 5'-deiodinase enzyme; PTU, propylthiouracil; rT3, reverse T3; Tx, thyroidectomized rats; T4, thyroxine; T3, triiodothyronine; 5'D-II, type II 5'-deiodinase enzyme.

(7); the drug inhibits the enzyme whether it is added in vitro or given in vivo (8). PTU injected into thyroidectomized-T4-replaced rats reduces serum T3 by 60–70% (9), although in similarly treated animals, T4 to T3 conversion in liver and kidney is reduced ~90% (10, 11).

Recently, we have observed that [125 I]T4 to [125 I]T3 conversion in vivo is different in various tissues (12). In cerebral cortex, cerebellum, and pituitary all [125 I]T3 formed in situ is insensitive to the inhibition by PTU, whereas in the liver and serum of the same animals, pretreatment with PTU reduces the accumulation of [125 I]T3 by 60%. In vitro studies have shown that the former tissues indeed have a unique iodothyronine 5'-deiodinase, which is different from the one present in liver and kidney in many respects, among others, being insensitive to PTU and having a low apparent K_m (1–2 nM) for the substrates T4 and reverse T3 (rT3) (13, 14). We have termed this enzyme type II 5'-deiodinase (5'D-II) to differentiate from the liver and kidney 5'-deiodinase enzyme, 5'D-I. Brown, but not white, adipose tissue has recently been found to contain significant quantities of 5'D-II (15) but our efforts to demonstrate measurable amounts of this enzyme in other tissues, including liver and kidney, have been unsuccessful. Another important characteristic of 5'D-II is that the tissue levels increase as serum T4 decreases (16). Thus, 5'D-II is 4–5-fold more abundant in the cerebral cortex, pituitary, and brown adipose tissue (BAT) from hypothyroid than in euthyroid adult rats. In contrast, 5'D-I activity is reduced by 50% in hypothyroid and euthyroid liver and kidney.

The incomplete inhibition of serum and liver T3 accumulation in vivo suggests that as much as 30–40% of the serum T3 generated from T4 may occur via 5'D-II in euthyroid rats (8, 9, 12). Given the changes in 5'D-I and 5'D-II observed in hypothyroidism, a larger fraction of T4 could be converted to T3 via this pathway. When T4 is provided to thyroidectomized rats (Tx) the fraction converted to T3 could be normal, or even increased, in spite of a reduction of 5'D-I activities in kidney and liver. The ensuing studies were undertaken to answer the question of whether or not 5'D-II is an important pathway of peripheral T3 production in hypothyroidism.

Methods

Male adult Sprague-Dawley rats (Zivic Miller, Allison Park, PA or Charles River Breeding Labs Inc., Wilmington, MA) were used throughout. Thyroidectomy followed by parathyroid reimplant was performed by the supplier (Zivic Miller). Rats were used at least 6 wk after thyroidectomy, the completeness of which was confirmed by reduced serum T4 and T3 concentrations.

[125 I]T4 (sp act ~ 4,200 μ Ci/ μ g), [131 I]T3 (sp act ~ 2,800 μ Ci/ μ g), and [125 I]rT3 (sp act ~ 2,800 μ Ci/ μ g) were prepared in the laboratory after procedures previously published with only minor modifications (17, 18). Tracers were stored at 0–4°C in 70% ethanol and used within 1 wk of synthesis. At the time of injection, the appropriate volume was dried under N_2 and resuspended in 0.9% NaCl/normal rat serum (9:1) containing 10 mg/ml NaI. Tracers were injected intravenously, usually mixed, in boluses of 0.1 or 0.2 ml/rat.

Unlabeled T4 and rT3 were injected intraperitoneally or intravenously

in the same vehicle as the tracers, at concentrations calculated to deliver the desired amount in 0.1 ml/100 g body weight (bw). Doses, time, and site of injection are indicated with the description of each experiment.

PTU was dissolved in 1.5 N NaOH, in one-tenth of the final volume, and then diluted with water to the desired concentration to inject a 0.1–0.2 ml/100 g bw; when necessary, pH was reduced to 10–11 with H_3PO_4 . All injections were given intraperitoneally in doses and at times indicated for individual experiments.

In vivo studies of T4 and T3 distribution and disposal. Fractional T4 to T3 conversion. Euthyroid or hypothyroid rats were injected with 60–100 μ Ci of [125 I]T4 and 20 μ Ci of [131 I]T3 and serum levels of [125 I]T4, [131 I]T3, and [125 I]T3 from T4 ([125 I]T3[T4]) were measured for 24 h. Five-tenths to 0.6 ml of blood was obtained from the heart under light ether anesthesia. Two experiments, I and II, were performed in euthyroid rats and one using hypothyroid rats. In experiment I, three groups of three, and in experiment II and that with hypothyroid rats, four groups of four rats were bled alternatively between 30 and 24 h after the tracers were injected. Thus, each group of rats was bled no more than three times with an interval of at least 3 h to avoid the stress of repeated bleeding. The detailed schedules of bleeding are presented under Table I.

Serum [125 I]T4 and [131 I]T3 were separated by paper chromatography. When there were >1,000 cpm of the least abundant isotope in 20 μ l of serum, this volume was directly applied to chromatography paper (Whatman filter paper no. 3 MM) and followed, while still wet, by 50 μ l of ethanol/2 N NH_4OH (9:1) containing 2 mg/ml T4, T3, and NaI (marker). The latter were used as markers for chemical stains. When fewer than the above number of counts were present, the appropriate volume of serum (30–50 μ l) was extracted with 50 μ l of marker and 100 μ l of butanol saturated with 2 N NH_4OH ; the precipitate was reextracted with 150 μ l ethanol/butanol (1:2) saturated with 2 N NH_4OH , the extracts pooled and applied to paper. This procedure allowed overall extraction of >90% of the counts. Chromatograms were developed for 18–24 h in tertiary amyl alcohol/hexane/2 N NH_4OH (5:1:6). 20–50 μ l of each serum were counted along with the T3 and T4 spots from the chromatograph and the radioactivity expressed as percent injected dose per milliliter. The concentrations of [125 I]T4 and [131 I]T3 were calculated from the total serum radioactivity and the fraction of counts recovered as [125 I]T4 and [131 I]T3 in the corresponding spots.

Serum [125 I]T3 was measured by a combination of affinity and paper chromatography (19). The serum (0.1 ml) was first chromatographed through a 0.3-ml bed-volume-column of Sepharose to which anti-T3 antibody had been conjugated. After elution of non-T3 counts with 0.1 M Na-phosphate buffer, pH 7.1, both [125 I]T3 and [131 I]T3 were eluted with methanol/2 N NH_4OH (9:1). The eluates were dried under N_2 and applied to paper. This step reduces markedly the [125 I]T4 to [125 I]T3 ratio. Typically, 50–60% of the ^{125}I -counts in the eluate are [125 I]T3, 30–40% [125 I]T4, and the rest are distributed evenly along the rest of the paper strip; 85% of the ^{131}I -counts are [131 I]T3. The latter was used as an internal recovery standard since the total concentration in the serum was known from direct chromatography. Recovery of T3 in the eluates was 50–60%. The concentration of [125 I]T3 was then expressed as percentage of the [125 I]T4 injected. This figure was corrected for the small amount of [125 I]T3 contaminating the injected [125 I]T4 as follows: since the distribution and clearance of this radiolabeled T3 is the same as that of simultaneously injected [131 I]T3, and the concentration of the latter was known for each sample, the serum concentration of [125 I]T3 injected, i.e., contaminating the [125 I]T4, could be calculated: (percent [125 I]T3 in [125 I]T4 dose \div 100) \times (serum [131 I]T3), expressed as percentage of the [131 I]T3 dose. This number was subtracted from the observed

[¹²⁵I]T3. The residual [¹²⁵I]T3 counts were multiplied by two because of the loss of one atom of ¹²⁵I in the process of conversion. Contaminating [¹²⁵I]T3 was <10% of the total [¹²⁵I]T3 at all times after 2 h post injection.

In the above extraction procedure, the serum samples were thawed and immediately put in the T3-antibody Sepharose column. Over 95% of the [¹²⁵I]T4 did not bind to the column, i.e., came out in the first eluate, whereas >60% of the [¹²⁵I]T3 and [¹³¹I]T3 remained bound to the fixed antibody. To determine whether there was artifactual T4 to T3 conversion during this procedure, the first eluate from one column, containing ~95% of the [¹²⁵I]T4 and <60% of the [¹²⁵I]T3 was rechromatographed successively through three columns. Each of the columns was handled as described above for the serum samples. One-fourth of 1% of the ¹²⁵I-counts were T3 after the first column, as per the second column; this figure decreased to 0.10%, and became negligible in the subsequent columns, which indicated there was no artifactual conversion. Had conversion taken place, a constant percent of [¹²⁵I]T4 put into each column would have been recovered as [¹²⁵I]T3.

The serum concentrations of all three radiolabeled iodothyronines were normalized to 200 g to avoid this source of variation. In all four experiments performed to determine kinetic parameters the early serum concentrations correlated inversely with the body weight (coefficients of correlation ranging from -0.84 to -0.97). The weights of the animals are given in Table I.

The data on [¹³¹I]T3 and [¹²⁵I]T4 were analyzed by noncompartmental analysis (20, 21); the fractional conversion was also calculated based on the same principles. It was assumed that the clearance of T3 entering the bloodstream was the same regardless of the site and rate of entrance. Support for this assumption has been obtained from the comparison of the serum concentrations of [¹²⁵I]T3 injected intravenously with those obtained from simultaneous subcutaneous injection of [¹³¹I]T3 in 0.1 ml of human serum (Silva, J. E., submitted for publication). The areas under the curves described by both radiolabeled T3's were identical and, since the absorption of the subcutaneously injected T3 was complete, the clearances were also identical. Thus, the areas under the curves from time 0 to infinity of [¹²⁵I]T3(T4), T3 derived from [¹²⁵I]T4, and [¹³¹I]T3 should be proportional to the respective "doses"; i.e., the area under the curve of [¹²⁵I]T3(T4) should be proportional to the fraction of the total [¹²⁵I]T4 converted to T3: dose [¹²⁵I]T3(T4) = \int_0^∞ [¹²⁵I]T3(T4)dt ÷ \int_0^∞ [¹³¹I]T3(T4)dt × 100 = percent of [¹²⁵I]T4 converted to [¹²⁵I]T3.

The integrated serum concentrations of both radiolabeled T3's were obtained by direct planimetry from 0 to 24 h after the injections and thereafter were calculated assuming that the levels decreased approaching a single exponential (20, 21). In the case of [¹²⁵I]T3(T4) the terminal slope approaches that of the precursor, [¹²⁵I]T4:

$$\int_{24}^{\infty} [^{125}\text{I-T3(T4)}]dt = \int_{24}^{\infty} [^{125}\text{I-T3(T4)}] \times e^{-\lambda_4 t} dt = \frac{[^{125}\text{I-T3(T4)}]_{24}}{\lambda_4},$$

where [¹²⁵I-T3(T4)]₂₄ is the serum concentration of [¹²⁵I]T3(T4) at 24 h, and λ₄ is the fractional removal rate of T4.

The error of this approximation ultimately depends on the time at which the rate of decrease of serum [¹²⁵I]T3(T4) becomes indistinguishable from λ₄. In turn, this time depends on the differences between λ₃ and λ₄, the fractional rates of disappearance of T3 and T4, respectively, and on how much [¹²⁵I]T4 remains at 24 h. Because of the rapid disappearance of [¹³¹I]T3 and [¹²⁵I]T4, and the difference between λ₃ and λ₄ in euthyroid animals, the error is minimal. However, in hypothyroid rats (see Table I and Fig. 2) the rate of disappearance of [¹²⁵I]T3(T4) is still <λ₄ at 24 h and, therefore, a significant error may result. As shown in Appendix

II, correcting the error in this approximation requires multiplying the $\int_{24}^\infty [^{125}\text{I-T3(T4)}]dt$ by 1.26.

Effect of PTU on T4 to T3 conversion. PTU was injected in various dosages to find the lowest dose that would decrease liver and kidney 5'-deiodinase by >90% and in subsequent experiments was given in doses equal or greater than that dose. The effect of the drug was assessed in vivo by tracer T4 to T3 conversion as well as by T3 accumulation after different doses of unlabeled T4. To assess further the source of serum T3 after T4, 5'D-II was also manipulated by pretreating hypothyroid rats with reverse T3 in doses that are maximally inhibitory for 5'D-II (22).

Radioimmunoassay (RIA). Serum T4 and T3 were measured by previously described radioimmunoassays (23) using rat thyroid hormone-free serum in the standard curve for T3 and human thyroid hormone-free serum for T4.

Enzyme assays. Iodothyronine 5'-deiodinase type I and II were measured as previously described (12). Type II 5'D is defined as T4 to T3 converting activity or rT3 5'-deiodination in the presence of 1 mM PTU; the two methods give identical results (12, 16). Enzyme activity was assayed in crude homogenates or the infranats of brown adipose tissue homogenates (15).

Statistical analysis was performed by paired and unpaired *t* tests and analyses of variance when indicated.

Results

T4 and T3 kinetics in euthyroid and hypothyroid rats. Disappearance curves of [¹²⁵I]T4 and [¹³¹I]T3 are shown in Fig. 1. The results of the two experiments done in euthyroid rats are depicted by different closed symbols.

The kinetic parameters derived from the data in Fig. 1 are shown in Table I. Since the parameters obtained by noncompartmental analyses are the composite figure obtained from the integrated plasma concentrations of several groups of rats in each experiment, there was no way to assess the statistical level of significance of the differences. However, the close agreement between the figures obtained by single compartmental analyses with those obtained by noncompartmental analyses allowed us to get an estimate of the significance of some of the differences. Although both the volume of distribution of T4 and the fractional removal rate of T3 were significantly reduced in hypothyroidism, the reduction in T4 volume of distribution was dependent upon the modeling because the value obtained by noncompartmental analyses in hypothyroid rats was not different from that observed in euthyroid rats. The reduction of the rate of irreversible removal of T3 in hypothyroid rats seemed clear and independent of the modeling. Notwithstanding all the restrictions in the statistical analyses, the calculated clearance of T3 and T4 by noncompartmental analyses were 40–50% reduced in hypothyroidism.

The curves describing the appearance of the serum [¹²⁵I]T3(T4) are shown in Fig. 2. In euthyroid rats we observed an early peak followed by a broader wave of accumulation, whereas in hypothyroid rats such an early peak was not seen. However, the calculated fractional T4 to T3 conversion was ~22% in euthyroid and ~26% in hypothyroid rats. As shown in Table I, since the fractional removal rate of [¹²⁵I]T4 was

Figure 1. Time course of disappearance of $[^{125}\text{I}]\text{T}_4$ and $[^{131}\text{I}]\text{T}_3$ from the serum after the intravenous injection of both tracers. Concentrations are expressed as percent dose per milliliter normalized to 200 g bw. The open circles are data from hypothyroid rats and the closed symbols result from two different experiments performed in euthyroid rats. In these experiments, groups of three rats (experiment I euthyroid rats, filled circles), or four rats each (experiment II euthyroid rats, filled squares, and hypothyroid rats, open circles), were bled two or three times with the schedule described in Table I.

reduced in hypothyroid rats, the fraction of T4 converted to T3 per day was $\sim 15\%$ in both euthyroid and hypothyroid rats.

Effects of PTU on extrathyroidal T3 production in euthyroid and hypothyroid rats. We used PTU to explore the enzymatic pathway of extrathyroidally generated serum T3 in euthyroid and hypothyroid animals. In the experiment shown in Table II, euthyroid and hypothyroid rats were given 2 mg of PTU/100 g bw 4 h before and at the time of $[^{125}\text{I}]\text{T}_4$ and $[^{131}\text{I}]\text{T}_3$ injections. Serum $[^{125}\text{I}]\text{T}_4$, $[^{125}\text{I}]\text{T}_3(\text{T}_4)$, and $[^{131}\text{I}]\text{T}_3$ were measured 4 and 22 h after injection. At both times, serum $[^{125}\text{I}]\text{T}_4$ and $[^{131}\text{I}]\text{T}_3$ concentrations were higher in hypothyroid rats ($P < 0.001$), but PTU did not affect the concentrations of these iodothyronines in either state. While at 4 h the serum concentration of $[^{125}\text{I}]\text{T}_3(\text{T}_4)$ was not affected by hypothyroidism, at 22 h it was higher in hypothyroid animals, which was consistent with the data in Fig. 2. Pretreatment with PTU reduced the serum concentration of $[^{125}\text{I}]\text{T}_3(\text{T}_4)$ in euthyroid rats by 75% at 4 h ($P < 0.005$), and by 44% at 22 h ($P < 0.025$). In contrast, this drug did not reduce the serum $[^{125}\text{I}]\text{T}_3(\text{T}_4)$ concentration in hypothyroid rats. Because of the decreased clearance of T3 in hypothyroidism (Fig. 1, Tables I and II), the ratio of $[^{125}\text{I}]\text{T}_3(\text{T}_4)/[^{131}\text{I}]\text{T}_3$ was considered a more accurate reflection of T4 to T3 conversion. In agreement with the similar fractional

T4 to T3 conversion rates between euthyroid and hypothyroid rats (Table I), thyroid status did not affect this ratio. In euthyroid rats, PTU pretreatment resulted in a 70% ($P < 0.010$) and 56% ($P < 0.005$) reduction in the $[^{125}\text{I}]\text{T}_3(\text{T}_4)/[^{131}\text{I}]\text{T}_3$ ratio at 4 and 22 h, respectively, while it had no effect on this ratio in hypothyroid rats at either time interval. As shown below, PTU at this dosage caused $>90\%$ inhibition of 5'D-I in liver and kidney.

Demonstration of a PTU-induced reduction in extrathyroidal T3 production after high doses of exogenous T4. Because of the roughly 100-fold lower apparent K_m of 5'D-II (10–13), and the marked increase in this enzyme in the cerebral cortex, pituitary, and BAT of the hypothyroid rats, the generation of serum T3 after different doses of T4 and the effect of PTU thereon were studied. Rats were injected with 1, 2, or 10 μg of T4/100 g bw and serum levels of T4 and T3 were measured by RIA 24 h later. The results are shown in Table III. The hypothyroid state of the animals is well documented by the low basal levels of serum T4 and T3. When 1 μg of T4/100 g bw was injected, pretreatment with PTU in various doses did not affect the increment in serum T3. When the dose of T4 was increased, PTU significantly inhibited T4 to T3 conversion. Furthermore, when 10 μg T4/100 g bw was injected, the serum T4 concentration was ten times higher than after 1 μg was injected, but the increment in T3 was barely two times that found with 1 μg T4/100 g bw, which suggested a decreased fractional conversion. The increment in serum T3 was $\sim 60\%$ less when rats receiving 10 μg T4/100 g bw were pretreated with PTU ($P < 0.001$). Regardless of the dose of T4, PTU in the various dosages reduced liver 5'D-I activity $>85\%$ and the kidney 5'D-I enzyme was $>90\%$ inhibited by doses of PTU of 2–6 mg/100 g bw (Table III).

Effect of reverse T3 (rT3) on extrathyroidal T3 production in hypothyroid rats. Since rT3 is a potent inhibitor of 5'D-II in cortex and pituitary and has the advantage that it is rapidly cleared (22), we used this iodothyronine to see the effect of decreasing 5'D-II on T4 to T3 conversion in hypothyroid rats. In the experiment shown in Table IV, thyroidectomized rats were given 30 μg rT3/100 g bw; the controls were injected with 50 ng T4/100 g bw. This was the maximum amount of T4 that could contaminate the rT3, based on T4 RIA. At 4 h, when the effect of rT3 on 5'D-II is maximal (22), the serum rT3 concentration is <2 ng/ml. This was estimated from the concentration of tracer $[^{125}\text{I}]\text{rT3}$ that was given together with the unlabeled rT3. At this time, $[^{125}\text{I}]\text{T}_4$ and $[^{131}\text{I}]\text{T}_3$ were injected and the rats killed 3 h afterwards. 7 h after the injection of rT3, 5'D-II was still significantly inhibited in all three tissues by $>60\%$ ($P < 0.05$, Table IV). The serum concentration of $[^{125}\text{I}]\text{T}_3(\text{T}_4)$ was significantly reduced, as was the $[^{125}\text{I}]\text{T}_3(\text{T}_4)/[^{131}\text{I}]\text{T}_3$ ratio, but neither $[^{125}\text{I}]\text{T}_4$ nor $[^{131}\text{I}]\text{T}_3$ concentrations were affected by the pretreatment with rT3.

Discussion

T4 and T3 kinetics and T4 to T3 conversion in hypothyroid rats. The clearance rates of T4 and T3 were reduced by 45–

n, number of pairs used to calculate the regression lines in the single compartment analyses. NCA, noncompartmental analyses; SCA, single compartmental analyses; VD, volume of distribution; λ, fractional removal rate; and Cl, clearance. All serum concentrations were normalized to 200 g bw (see Methods); therefore, VD and Cl correspond to a 200 g rat. Rats were injected with [¹²⁵I]T4 and [¹³¹I]T3 into the external jugular vein, and bled at different times after the injections by cardiac puncture under light ether anesthesia. Bleedings were performed as follows: Blood sample collection (see Methods): Experiment I: Three groups of three rats each, A, B, and C, were bled with the following schedule: A at 1, 12, and 24 h; B at 9 and 20 h; and C at 4 and 15 h. Experiment II: Four groups of four rats each, A, B, C, and D were bled with the following schedule: A at 2, 8, and 24 h; B at 4 and 12 h; C at 6 and 18 h; and D at 15 and 20 h. Hypothyroid rats: Four groups of four rats each, A, B, C, and D, were bled with the following schedule: A at 0.5, 6, and 24 h; B at 1 and 8 h; C at 2 and 12 h; and D at 4 and 16 h. * Statistical analyses. The probability of significance is given only for parameters calculated by SCA; the figures in parentheses indicate the 95% confidence limits. Since parameters obtained by SCA are composite figures, i.e., obtained from curves generated by the means of independent observations, no statistical analyses are possible. ‡ Based on our method of analysis, fractional conversion of T4 to T3 means percentage of total [¹²⁵I]T4 disposed of converted to [¹²⁵I]T3, with no time frame. The lower figures have taken into consideration that the total residence time of [¹²⁵I]T4 in the hypothyroid rats is prolonged. The figures have been obtained by multiplying the total conversion rates above by the fraction of [¹²⁵I]T4 metabolized per day, $1 - e^{-\lambda_4 \times 24}$, where λ₄ is the fractional removal rate of T4 in hours⁻¹.

50% (Table I) in hypothyroid rats. Although it was not possible to assess directly the statistical significance of this reduction, the magnitude of it and the variance of the primary data (Fig. 1) suggest that the clearances are significantly different. The reduction may reflect the combined effect of the generalized slowing of many metabolic processes in this condition, the spe-

cific decrease in the hepatic and renal iodothyronine degradation observed in this state (24–26), and the increase in plasma binding of iodothyronines observed in hypothyroidism. Thus, in seven pairs of samples taken randomly from rats used in these experiments, the dialyzable fraction of T4 was reduced to 60±3.6% and that of T3 to 74±3% of the corresponding values found in

Figure 2. Time course of appearance of [¹²⁵I]T3 in the serum after injecting [¹²⁵I]T4 into euthyroid and hypothyroid rats. These results are from the same rats shown in Fig. 1 and symbols and explanations are the same. The serum concentrations of [¹²⁵I]T3(T4) have also been normalized to 200 g bw. The contributions of contaminating [¹²⁵I]T3 in the [¹²⁵I]T4 dose to each time point have been subtracted and the residual [¹²⁵I]T3 activity multiplied by two to correct for the loss of specific activity during T4 to T3 conversion.

the euthyroid sera (T4 = $[5.3 \pm 0.9] \times 10^{-4}$ and T3 = $[47 \pm 5] \times 10^{-4}$; $P > 0.001$).

The pattern of appearance of [¹²⁵I]T3(T4) in plasma was different in euthyroid from that in hypothyroid rats (Fig. 2).

While in the latter there was a slow rate of accumulation, in the former there was an early peak of [¹²⁵I]T3(T4) followed by a broader wave of [¹²⁵I]T3(T4) accumulation. In agreement with this observation, Table II shows that 4 h after the [¹²⁵I]T4 injection serum [¹²⁵I]T3 was greater than at 22 h in euthyroid rats, whereas the opposite was observed in hypothyroid rats. We have made the same observation in 2-wk-old euthyroid rats (Silva, J. E., submitted for publication) and observed the same pattern when sequential bleedings have been analyzed in individual euthyroid rats (not shown). Although we do not have a definitive explanation for this phenomenon, we postulate that the early peak represents a rather large amount of [¹²⁵I]T3(T4) rapidly transferred into the circulation, formed in pools like liver and kidney that exchange T3 rapidly with plasma (27–29). The appearance of this peak is probably related to several features such as the bolus nature of the injection, the characteristics of the uptake of [¹²⁵I]T4 by liver and kidney, the rate of conversion to [¹²⁵I]T3(T4), and the rate of transfer of this T3 into the circulation. Since the technique of the tracers injections was the same in all experiments, the absence of the peaks in hypothyroid rats has to be related to the other factors, one of which, the decreased T4 5'-diodinating activity of the liver and kidney, is well documented (24–26). However, we do wish to imply that the magnitude of this peak represents the total contribution of these rapid compartments to serum T3(T4), since the influx of [¹²⁵I]T3(T4) from these sources will continue

Table II. Effects of PTU and Thyroid Status on [¹²⁵I]T4, [¹²⁵I]T3(T4), and [¹³¹I]T3 Serum Concentrations in Adult Euthyroid and Hypothyroid Rats Given [¹²⁵I]T4 and [¹³¹I]T3

Each cell is the mean±SEM of four rats. All concentrations are expressed as percentage of the dose per milliliter. [¹²⁵I]T3(T4), the T3 produced from T4, has been corrected for the contaminating [¹²⁵I]T3 in the [¹²⁵I]T4 (0.75%) and for the 50% decrease in specific activity during T4 to T3 conversion. It is expressed as percentage of the [¹²⁵I]T4 dose per milliliter. The effect of PTU and thyroid status on each parameter was analyzed by two-way analysis of variance.

* In experiment I, T4 was given intraperitoneally; in experiments II–IV, T4 was injected intravenously. ‡ PTU was always injected intraperitoneally. In experiments I and III, the total dose was injected ~1 h preceding the T4, and in experiments II and IV it was injected in three doses of 2 mg/100 g bw each at 6, 4, and 2 h before the T4 dose. § Basal serum T4 was not significantly different from zero in all groups.

thereafter and mix with [¹²⁵I]T3(T4) that appears in the circulation from other sources.

The magnitude of fractional conversion in euthyroid rats, 22% of the [¹²⁵I]T4 disposed of, is in agreement with figures previously reported by others in euthyroid rats (3, 28, 29). However, based on previous data showing a decreased rate of T4 disappearance in hypothyroid rats (30), as confirmed here, and based on the well documented decreased iodothyronine 5'-deiodinase activity in hypothyroid liver and kidney (24–26), the finding of 26% of the [¹²⁵I]T4 converted to T3 in hypothyroid rats was surprising. Even when the decreased rate of metabolism of T4 in these rats is taken into consideration, the fraction of [¹²⁵I]T4 converted to [¹²⁵I]T3 per day is not different from that calculated for the hypothyroid rats (Table I). This indicates that the slower rate of disappearance of T4 in hypothyroid rats is due to a decreased rate of metabolism by pathways other than 5'-deiodination, and suggests, as discussed below, that there is a shift in the source of extrathyroidal T3 production as a consequence of hypothyroidism.

Failure of PTU to reduce T4 to T3 conversion in hypothyroid rats. PTU in dosage regimens similar to the ones used in these experiments reduces extrathyroidal T4 to T3 conversion in euthyroid rats by 60–70% (9, 12), as corroborated in the present experiments (Table II). This incomplete inhibition suggests that even in euthyroid rats, a fraction of the extrathyroidally produced

serum T3 may be generated via a PTU-insensitive pathway. Since 5'D-II activity is increased in hypothyroidism and is insensitive to PTU, conversion by this enzyme certainly could explain the shift of the source of extrathyroidally generated T3 from a predominantly 5'D-I pathway in euthyroidism to a predominantly 5'D-II one in the hypothyroid state.

In hypothyroid rats, 2 mg PTU/100 g bw inhibited liver and kidney 5'D-I >90% for 24 h (Table III). Despite this inhibition, extrathyroidal T3 generation was not affected. Increasing the dose to as much as 6 mg PTU/100 g bw in three doses before the injection of T4 did not decrease the increment in serum T3 after a 1 μg/100 g bw dose of T4 (Table III, experiment II). These results suggest that 2 mg PTU/100 g bw is a maximal dose *in vivo*.

Effect of the dose of T4 on T4 to T3 conversion rates and on the sensitivity to PTU in hypothyroidism. The similar fractional [¹²⁵I]T4 to [¹²⁵I]T3 conversion in euthyroid and hypothyroid rats may be related to the higher specific activity of the tracers in the rats lacking endogenous T4. On the other hand, 5'D-II has a low apparent K_m for T4 and is rapidly suppressed by T4, T3, and rT3 (22). It was therefore conceivable that by giving T4 in higher doses, 5'D-II would be reduced and PTU would become effective in reducing the rate of fractional conversion due to recruitment of the higher K_m , PTU-sensitive 5'D-I pathway. The experiment in Table III shows that after 1 μg

* Chronic Tx were injected with 30 µg/100 g bw of rT3. Controls were given 50 ng/100 g bw T4 (the maximal amount of T4 possible as a rT3 contaminant). 4 h later the animals were injected with [¹²⁵I]T4 and [¹³¹I]T3 and killed 3 h afterwards. Type II 5'-deiodinase was measured as described in Methods in homogenates of the indicated tissues. Either rT3 in the presence of 1 mM PTU or T4 were used as substrates. Labeled iodothyronines in cortex and serum were separated as described in Methods. The concentrations of [¹²⁵I]T3 have been corrected for the amount of [¹²⁵I]T3 contaminating [¹²⁵I]T4 (0.1%) and for the 50% decrease in specific activity of [¹²⁵I]T3 during T4 to T3 conversion.

‡ Both substrates were used at 2 nM in the enzyme assay.

§ All concentrations are expressed as percentage of dose of the injected tracer per milliliter of serum.

T4/100 g bw, PTU did not reduce the formation of T3, but when the dose was increased, PTU did become effective. Furthermore, at 10 µg T4/100 g bw there was a substantial fall in fractional T4 to T3 conversion. These results suggest that the mechanism producing T3 from T4 in hypothyroid rats is easily saturated or suppressed at T4 doses higher than the euthyroid daily production rate of 1 µg/100 g. Since over this dose range fractional conversion is decreased and becomes inhibitable by PTU, we can conclude that at up to physiological replacement doses, 5'D-II is the predominant pathway in hypothyroid rats, and that only upon saturation or suppression of 5'D-II is the 5'D-I pathway made evident.

Effects of inhibiting 5'D-II upon [¹²⁵I]T3 generation from [¹²⁵I]T4. Since cortex and pituitary 5'D-II is rapidly and markedly inhibited by reverse T3 (22), we used this iodothyronine to decrease the activity of 5'D-II. In agreement with the reduction in 5'D-II activity, [¹²⁵I]T3 accumulation was reduced in the

serum. This contrasts with the lack of effect of PTU, which inhibits 5'D-I by >90%, and is therefore consistent with our hypothesis that 5'D-II is a major source of [¹²⁵I]T3(T4) in hypothyroid rats.

Leonard and Rosenberg (31) have reported an early phase in 5'-deiodination in kidney membranes (5'D-I) that is PTU-insensitive and thiol-independent. This phase, which lasts only a few seconds, is thought to be due to the presence of small quantities of enzyme with the active thiol groups in reduced form. Once the enzyme interacts with the substrates, T4 or rT3, sulfenyl iodides are formed and PTU interacts with them, forming mixed disulfide bonds and inactivating the enzyme. It is then conceivable that our results are due to this phenomenon; because of the lack of substrate in hypothyroid rats, most of the enzyme is in reduced form and, therefore, a substantial degree of 5'-deiodination ensues before the enzyme becomes sensitive to PTU. The results of the experiment just described, in which rats were pretreated with rT3, along with the lack of effect of PTU after 1 µg of T4/100 g bw (Table III) and the time course of [¹²⁵I]T3 appearance after [¹²⁵I]T4 in hypothyroid PTU-treated rats (Table II), altogether make this potential explanation extremely unlikely.

Of the three tissues known to contain 5'D-II, the brown adipose tissue is the most likely to be an important source of serum T3, since it is well perfused (32) and relatively abundant in the rat (33). Assessment of the contribution of BAT 5'D-II to plasma T3 is presently under investigation. Although our efforts to demonstrate 5'D-II in other tissues (liver, kidney, muscle, heart) have been unsuccessful, its presence in low concentrations in these larger organs or tissues has to be kept in mind. Wherever the enzyme is located, the combined results with PTU and rT3 indicate that 5'D-II can serve as a source of plasma as well as of intercellular T3. It is clearly the major source of extrathyroidally produced T3 in the hypothyroid rat, and probably a significant source in the euthyroid animal as well.

Physiological implications of these studies for man. Our findings are in agreement with observations by Morris et al. (34) that suggest increased fractional T4 to T3 conversion in hypothyroxinemic humans, and with the earlier observations of Inada et al. (35) indicating normal or increased fractional T4 to T3 conversion in hypothyroidism in man. In addition, these results provide a physiological rationale for the initial therapy of hypothyroid patients with comparatively small amounts of T4 (~100 µg/24 h) (36) rather than T3 (37) or larger doses of T4 (38), until the liver and kidney recover their capacity to catalyze T4 to T3 conversion. Such doses of T4 would maintain a more efficient T4 to T3 conversion and, equally important, would facilitate production of T3 in the cerebral cortex, where, at least in the rat, ~75% of the T3 is produced locally in a reaction catalyzed by 5'D-II (39). A large dose of T4 (or T3) would inhibit the cerebrocortical 5'D-II and would impair local T3 generation in this tissue (22), and might decrease the overall fractional conversion in a situation where most of serum T3 may be generated by 5'D-II.

Dose [¹²⁵I]T4 ([¹²⁵I]T4D)/64,000,000 cpm. Dose [¹³¹I]T3([¹³¹I]T3D)/34,000,000 cpm. * 2- and 24-h samples belong to rat No. 1, 260 g bw; 15-h sample belongs to rat No. 12, 228 g bw. ‡ All samples counted to ≤1% counting error. § Crude cpm/ml of serum in paper chromatograms of methanol/NH₄-eluates from Sepharose-T3Ab columns.

[¹²⁵I]T3 (percentage of [¹²⁵I]T4 dose per milliliter × 10³)

$$2 \text{ h} = \left(291 \div \frac{5,530}{45,900} \div [\text{¹²⁵I]T4D} \right) \times 100 \times 10^3 = 3.78.$$

$$15 \text{ h} = \left(980 \div \frac{2,420}{12,500} \div [\text{¹²⁵I]T4D} \right) \times 100 \times 10^3 = 7.90.$$

$$24 \text{ h} = \left(354 \div \frac{550}{2,620} \div [\text{¹²⁵I]T4D} \right) \times 100 \times 10^3 = 2.64.$$

Other corrections were (a) the [¹²⁵I]T3 contaminating the [¹²⁵I]T4 dose, 0.25% of the [¹²⁵I]T4 counts in this experiment: 64,000,000 × 0.0025 = 160,000 cpm injected [¹²⁵I]T3; (b) correction for loss of specific activity during 5'-deiodination (multiply by two); (c) normalization to 200 g bw.

$$2 \text{ h} = \left(3.78 - \frac{160,000}{[\text{¹²⁵I]T4D}} \times \frac{45,900 \times 100}{[\text{¹³¹I]T3D}} \times 10^3 \right) \times 2 \times \frac{260}{200} \\ = 8.95\%/ml (\times 10^3).$$

$$15 \text{ h} = \left(7.90 - \frac{160,000}{[\text{¹²⁵I]T4D}} \times \frac{12,500 \times 100}{[\text{¹³¹I]T3D}} \times 10^3 \right) \times 2 \times \frac{228}{200} \\ = 17.80\%/ml (\times 10^3).$$

$$24 \text{ h} = \left(2.64 - \frac{160,000}{[\text{¹²⁵I]T4D}} \times \frac{2,620 \times 100}{[\text{¹³¹I]T3D}} \times 10^3 \right) \times 2 \times \frac{260}{200} \\ = 6.81\%/ml (\times 10^3).$$

Appendix II

Integration of serum [¹²⁵I]T3(T4) concentrations from 24 h to infinity after the injections.

The amount of [¹²⁵I]T3(T4) at anytime (*t*) in the system, (QT34)*t*, expressed as a fraction of the [¹²⁵I]T4 dose can be defined by (3):

$$(QT34)t = (CR\lambda_4/\lambda_3 - \lambda_4) (e^{-\lambda_4 t} - e^{-\lambda_3 t}). \quad (\text{Equ. I})$$

Table VI. Integrated serum [¹²⁵I]T3(T4) and [¹³¹I]T3 Concentrations in Hypothyroid Rats ([Percentage of Doses Per Milliliter] × H)

Time period	[¹²⁵ I]T3(T4)	[¹³¹ I]T3
0–24 h	0.38	3.23
24–∞	0.59	1.15
24–∞ corrected	0.74	—
0–∞	1.12	4.38

Conversion (percentage) = (1.12 ÷ 4.38) × 100 = 25.6%.

Where CR is the conversion ratio, that is the fraction of the [¹²⁵I]T4 disappearing in any given interval that has been converted to [¹²⁵I]T3. This equation predicts that the apparent rate of disappearance of QT34 will eventually approach that of T4 at some time after the level of QT34 has reached a maximum. This time will depend on the difference between λ₃ and λ₄ and on their absolute values. In euthyroid rats (Figs. 1 and 2, and Table I) the concentration of [¹²⁵I]T3(T4) in the serum after 24 h decreases at a rate not markedly different from λ₄. The error resulting from dividing the serum concentration at 24 h by λ₄ to calculate the integrated concentration from 24 h to infinity is thus minimal. In contrast, it is apparent from Fig. 2 and from the magnitude of λ₄ and λ₃ (Table I), that such an approach might underestimate the integrated concentration of [¹²⁵I]T3(T4) after 24 h in the hypothyroid rats. From Equ. 1 we see that a plot of (e^{-λ₄t} - e^{-λ₃t}) vs. time will describe the approximation of the rate of reduction in the serum level of [¹²⁵I]T3(T4) to λ₄. By taking the same 24-h serum [¹²⁵I]T3(T4) value and allowing it to disappear at a rate of λ₄, one obtains the time course of reduction of [¹²⁵I]T3(T4) decaying at a rate that is not different from that of serum T4. The integration of both curves to infinity allows one to determine the magnitude of any error made by using λ₄ in the hypothyroid rats. The results of such a procedure with the values of λ₄ and λ₃ from Table I, indicate that indeed the error in euthyroid rats is insignificant, but in hypothyroid animals the area is 21% underestimated by applying λ₄ to the 24-h serum [¹²⁵I]T3(T4) to integrate it to infinity. Therefore, the 24 to infinity integral calculated with λ₄ was multiplied by 1.26 in hypothyroid animals (Table VI).
