## **Abstract**

### **Background**

Glucose-6-phosphate dehydrogenase (G6PD) deficiency decreases the ability of red blood cells (RBCs) to withstand oxidative stress. Refrigerated storage of RBCs induces oxidative stress. We hypothesized that G6PD-deficient donor RBCs would have inferior storage quality for transfusion as compared to G6PD-normal RBCs.

### **Methods**

Male volunteers were screened for G6PD deficiency; 27 control and 10 G6PD-deficient volunteers each donated one RBC unit. After 42 days of refrigerated storage, autologous 51-Chromium 24-hour post-transfusion RBC recovery (PTR) studies were performed. Metabolomics analyses of these RBC units were also performed.

### **Results**

The mean 24-hour PTR for G6PD-deficient subjects was  $78.5 \pm 8.4\%$  (mean  $\pm$  SD), which was significantly lower than that for G6PD-normal RBCs ( $85.3 \pm 3.2\%$ ;  $P=0.0009$ ). None of the G6PD-normal volunteers (0/27) and three G6PD-deficient volunteers (3/10) had PTR results below 75%, a key FDA acceptability criterion for stored donor RBCs. As expected, fresh G6PD-deficient RBCs demonstrated defects in the oxidative phase of the pentose phosphate pathway. During refrigerated storage, G6PD-deficient RBCs demonstrated increased glycolysis, impaired glutathione homeostasis, and increased purine oxidation, as compared with G6PD-normal RBCs. In addition, there were significant correlations between PTR and specific metabolites in these pathways.

### **Conclusions**

Based on current FDA criteria, RBCs from G6PD-deficient donors would not meet the requirements for storage quality. Metabolomics assessment identified markers of PTR and G6PD deficiency (e.g., pyruvate/lactate ratios), along with potential compensatory pathways that could be leveraged to ameliorate the metabolic needs of G6PD-deficient RBCs.

## Introduction

Red blood cell (RBC) transfusion is one of the most common therapeutic interventions for hospitalized patients.(1) In particular, chronic transfusions are essential for patients with sickle cell disease and thalassemia, due to intrinsic RBC defects and/or ineffective erythropoiesis in these patients. Accelerated clearance of transfused RBCs contributes to some adverse effects associated with chronic RBC transfusion therapy, such as iron overload, alloimmunization, and, possibly, increased susceptibility to infection.(2-6) As such, multiple efforts are directed towards providing optimal RBC products. The Food and Drug Administration (FDA) sets acceptability criteria for RBC units at the end of their maximum allowable storage period (e.g., 42 days), which are based primarily on a 24-hour post-transfusion recovery (PTR) of at least 75% on average (i.e., 75% of the transfused RBCs should still be circulating 24-hours later) and an *in vitro* hemolysis rate of less than 1%. Furthermore, the one-sided, lower limit of the 95% confidence interval for the proportion of “successful” PTRs (defined as  $\text{PTR} \geq 75\%$ ) must be  $\geq 70\%$  (i.e., no more than two “failed” PTRs of  $<75\%$  among a cohort of 20 healthy volunteer blood donors). Interestingly, PTRs vary significantly among blood donors(7) and these differences are specific and repeatable for each donor, suggesting that some donors are “good storers” and some are “poor storers.”(8) *In vitro* analyses of stored RBCs identified inter-donor metabolic heterogeneity, which can affect the metabolic age of a stored RBC unit at least as much as the chronological age of the unit.(5, 9) In addition, because RBC storage quality is heritable,(10-12) genetic factors may underlie at least some of this variation.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, an X-linked disorder, is the most common human enzymopathy, affecting ~400 million people worldwide.(13) In addition, G6PD is the rate-limiting enzyme of the pentose phosphate pathway (PPP), which generates reduced nicotinamide adenine dinucleotide phosphate (NADPH), a cofactor that drives multiple antioxidant pathways in RBCs.(14) Indeed, NADPH is critical for recycling oxidized glutathione (i.e., GSSG) to its reduced form (i.e., GSH) by glutathione reductase; in addition, it fuels multiple NADPH-dependent antioxidant enzymes (e.g., glutathione peroxidase, catalase, peroxiredoxins, glutaredoxins, the thioredoxin reductase system, biliverdin reductase B, and the ascorbate-tocopherol axis).(15) Because G6PD-deficient RBCs have a diminished capacity for producing NADPH,(16) they are susceptible to damage and destruction by increased oxidative stress, such as that caused by medications, infection, or diet.(17)

Oxidative stress biomarkers increase during refrigerated storage,(18, 19) suggesting that storage itself may cause oxidative stress. In addition, when RBCs are stored under hypoxic conditions(20) or in the presence of the antioxidant ascorbic acid,(21) which decrease oxidative stress, PTR significantly improves in humans and mice, respectively. Clearly, RBCs did not evolve to cope with the oxidant stress arising during refrigerated storage. However, RBCs have developed mechanisms to cope with oxidant stress during aging *in vivo*, and some of these are activated during routine blood bank storage. For example, studies with stable isotope-labeled tracers suggest that storage-induced oxidation of Cys152 of the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH) causes a shift in glucose metabolism towards the oxidative phase of the pentose phosphate pathway (PPP); this phenomenon is mitigated or aggravated by hypoxic or hyperoxic storage, respectively.(22)

Because G6PD is the key enzyme in the oxidative phase of the PPP, G6PD-deficiency limits NADPH production in RBCs, thereby decreasing their ability to regenerate GSH and prevent the accumulation of peroxidation/inflammatory products.(23) Indeed, glutathione homeostasis and antioxidant defenses are altered in units obtained from G6PD-deficient donors;(23, 24) however, these studies were only performed with donors carrying the Class II Mediterranean G6PD variant (<10% residual activity) and not with donors affected by the milder, but more common, Class III A- variant (10-60% residual activity); the latter affects ~10% of the African-American donor population.(25) Moreover, no study to date has evaluated the correlation of metabolomics changes in stored human G6PD-deficient RBCs to the “gold-standard” PTR outcome.

Although American blood donors are not routinely screened for G6PD deficiency, some blood collection agencies will exclude a prospective donor who reports a history of being G6PD-deficient. In a study from 1970, the PTR of stored G6PD-deficient RBCs was decreased in comparison to RBCs from G6PD-normal donors.(26) However, given the advent of modern additive solutions, which enhance RBC storage duration, and the introduction of leukoreduction, which mitigates the RBC storage lesion,(27) it is not known whether G6PD deficiency remains a source of variation in donor RBC storage quality. Because G6PD-deficient RBCs are part of the routine inventory of transfusion services (at a ~0.3% prevalence), and because chronically transfused patients with sickle cell disease require antigen-matched RBCs that frequently come from donors of African descent who have a high frequency of G6PD deficiency, the latter are more likely to receive G6PD-deficient RBC units (i.e., up to 12.3% of units transfused).(25) Therefore, transfusions of G6PD-deficient RBCs into

these patients may have reduced therapeutic efficacy.(28) Indeed, several case reports document adverse clinical outcomes following transfusion of G6PD-deficient RBCs,(29-31) raising the question of whether donors should be screened for G6PD deficiency.(32) The current study examined the storage quality of RBCs from G6PD-deficient and G6PD-normal donors, using 24-hour PTR as the primary outcome measure. Furthermore, correlations between metabolomics findings, G6PD activity, and PTR are provided.

## Results

### *Study participant demographics and recruitment*

A total of 145 male volunteers were screened for G6PD deficiency. To enrich for subjects with a greater probability of being G6PD-deficient, subjects of African, Asian, Hispanic, Mediterranean, and Middle Eastern descent, based upon maternal origin, were specifically recruited. Of the screened volunteers, 42 (29%) were of African descent, 32 (22.1%) were of Asian descent, 30 (20.7%) were Hispanic, 26 (17.9%) were of Mediterranean descent, 7 (4.8%) were of Middle Eastern descent, and 8 (5.5%) were Caucasian. Fifteen volunteers (10%) were G6PD-deficient and 130 (90%) were G6PD-normal. Of the G6PD-deficient volunteers, 10 were of African descent, 3 were of Mediterranean descent, and 2 were Hispanic. Ten G6PD-deficient (i.e., “deficient”) and 30 G6PD-normal (i.e., “control”) volunteers agreed to participate in the study and donated one unit of leukocyte-reduced RBCs stored in AS-3 (Figure 1). Two volunteers from the control group then withdrew from the study and 1 volunteer from the control group was excluded due to positive viral serologic testing following blood donation. Therefore, 27 control and 10 G6PD-deficient subjects completed the entire study; the demographics of these subjects are shown in Table 1.

G6PD enzyme activity levels for participating subjects are provided in Supplementary Figure 1. G6PD activity of  $\geq 9.9$  U/g Hb was considered normal based on the referral laboratory reference range. One control subject had a G6PD activity 12% less than the reference range (i.e., 8.7 U/g Hb), but *G6PD* exon sequencing did not identify any mutations. Although the presence of a rare splicing, promoter, or untranslated region mutation was not ruled out for this particular volunteer,(33) he was considered to be in the control, G6PD-normal group due to the proximity of his G6PD enzymatic activity to the lower limit of the reference range. Furthermore,

a sensitivity analysis categorizing this subject as G6PD-deficient did not change the primary outcome (data not shown). Overall, nine G6PD-deficient subjects were identified with the A- (Class III) variant and one with the Mediterranean variant (Class II). There were no significant differences in the mean baseline hemoglobin of control ( $14.6 \pm 0.8$  g/dL) and deficient ( $14.4 \pm 1.1$  g/dL) ( $P=0.53$ ) subjects, mean baseline hematocrit of control ( $43.1 \pm 2.2$  %) and deficient ( $42.3 \pm 2.9$  %) ( $P=0.40$ ) subjects, mean baseline mean corpuscular hemoglobin (MCH) of control ( $29.4 \pm 1.4$  pg) and deficient ( $30.5 \pm 1.6$  pg) ( $P=0.05$ ) subjects, and mean baseline mean corpuscular hemoglobin concentration (MCHC) of control ( $33.8 \pm 1.0$  g/dL) and deficient ( $33.9 \pm 0.9$  g/dL) ( $P=0.79$ ) subjects. In contrast the mean RBC count was significantly lower in deficient ( $4.72 \pm 0.38 \times 10^{12}/L$ ) than normal ( $4.96 \pm 0.25 \times 10^{12}/L$ ) ( $P=0.03$ ) subjects. The mean reticulocyte count of deficient subjects was significantly higher ( $2.2 \pm 0.8\%$ ) than control subjects ( $1.4 \pm 0.3\%$ ) ( $P<0.001$ ); however, it was still below the upper limit of normal for our laboratory's reference range (i.e., 2.26%). In addition, the mean corpuscular volume (MCV) was significantly higher in deficient ( $89.8 \pm 3.2$  fL) than normal ( $86.8 \pm 3.3$  fL) ( $P=0.02$ ) subjects and the red blood cell distribution width (RDW) was significantly lower in deficient ( $12.0 \pm 0.72$  %) compared to normal ( $12.8 \pm 0.71$  %) ( $P=0.009$ ) subjects. As expected, the mean G6PD activity of deficient subjects ( $2.4 \pm 0.9$  U/g Hb) was significantly lower than for controls ( $11.2 \pm 1.0$  U/g Hb) ( $p<0.001$ ; Table 1).

### *G6PD deficiency decreases PTR*

The 24-hr PTR for the 27 G6PD-normal subjects was  $85.3 \pm 3.2\%$  (mean  $\pm$  SD), as compared to  $78.5 \pm 8.4\%$  for the 10 G6PD-deficient subjects ( $P=0.0009$ ; Figure 2A). Although none of the RBC units in the control group (0/27) had a 24-hr PTR less than 75%, the key FDA

criterion for stored RBC quality, 3 G6PD-deficient RBC units (3/10) had PTRs below 75% (i.e., 63.7%, 68.0%, and 74.2%). Thus, based on this number of failures (3/10), RBC units collected from G6PD-deficient subjects, as a group, do not meet current FDA criteria for acceptability.(7) The PTRs stratified among subjects of African descent ( $86.6 \pm 2.0\%$  and  $78.5 \pm 8.8\%$  for G6PD-normal and G6PD-deficient, respectively;  $P < 0.05$ ; Figure 2B) and non-African descent ( $85.0 \pm 3.4\%$  and  $78.4 \pm 9.3\%$  for G6PD-normal and G6PD-deficient, respectively;  $P < 0.05$ ; Figure 2C) were similar. Finally, although there was an association between G6PD enzyme activity and PTR across all subjects ( $R^2 = 0.27$ ,  $P = 0.001$ ; Figure 2D), there was no significant association when adjusted for G6PD-status (i.e., variation in G6PD activity does not predict PTR among G6PD-deficient or G6PD-normal subjects when examined separately). Of note, the single subject with the Mediterranean variant and G6PD activity of 0.3 U/g Hb had a relatively normal PTR (i.e., 81.4%) despite having the lowest G6PD enzyme activity in the study population.

#### *G6PD deficiency decreases methemoglobin, but does not affect in vitro storage hemolysis*

Both control and G6PD-deficient RBCs had *in vitro* storage hemolysis rates of less than 1% throughout storage ( $0.29 \pm 0.18\%$  and  $0.24 \pm 0.07\%$  at 6-weeks, respectively; adjusted  $P = 0.79$  for difference; Figure 3A), thereby meeting another important FDA criterion of RBC storage quality. However, as compared to G6PD-normal units, a trend towards decreasing methemoglobin was observed over time in G6PD-deficient stored units ( $P = 0.086$ ); these differences were statistically significant after 3- and 6-weeks of storage (Figure 3B). Although there was also an increasing trend in lactate, and a decreasing trend in pH, glucose, and

sodium during storage, there were no differences between G6PD-deficient and control units (Figures 3C-F).

#### *G6PD-deficiency increases glycolysis*

At baseline (i.e., prior to refrigerated storage), metabolomics analyses of RBCs from G6PD-deficient volunteers show evidence of increased glycolysis as compared to G6PD-normal RBCs (Figure 4). Glycolytic intermediates, including bisphosphoglycerate (BPG), 2/3-phosphoglycerate (2/3PG), phosphoenolpyruvate (PEP), and lactate, were significantly increased in G6PD-deficient RBCs (all  $P < 0.01$ ; Figures 4B-D, and F). Consistent with these increases in glycolytic intermediates, G6PD-deficient RBCs also had significantly increased ATP levels ( $P < 0.01$ ; Figure 4G), as compared to controls. Pyruvate levels did not differ significantly between G6PD-deficient and G6PD-normal RBCs (Figure 4E).

#### *G6PD-deficient individuals cannot upregulate the oxidative branch of the PPP*

RBCs from G6PD-deficient individuals demonstrate a defective oxidative branch of the PPP (data are reported in tabulated form in Supplementary Tables 1 and 2, and in vectorial form in Supplementary Figures 2-4). These findings were confirmed by tracing experiments with [1,2,3- $^{13}\text{C}_3$ ] glucose, in the presence or absence of methylene blue, a PPP-stimulating agent (Figure 5A). Thus, by tracing heavy carbon moieties into glycolytic and PPP intermediates and byproducts (including isotopologues M+2 and M+3 of lactate), we confirmed that fresh G6PD-normal RBCs, but not fresh G6PD-deficient RBCs, could activate the oxidative branch of the PPP (Figure 5). Specifically, methylene blue treatment did not change [ $^{13}\text{C}_3$ ]-glucose phosphate levels in fresh or stored G6PD-deficient and G6PD-normal RBCs,

suggesting there was no difference in flux through the glycolytic pathway (Figure 5B). Nonetheless, methylene blue treatment increased [ $^{13}\text{C}_2$ ]-lactate levels and the ratio of [ $^{13}\text{C}_2$ ]-lactate/[ $^{13}\text{C}_3$ ]-glucose phosphate levels only in fresh G6PD-normal RBCs, suggesting increased flux through the PPP at baseline, but only in G6PD-normal subjects (Figure 5C,D;  $P < 0.05$ ). Stored G6PD-deficient and G6PD-normal RBCs were unable to activate the oxidative phase of the PPP (Figure 5C). Finally, in G6PD-deficient RBCs at baseline, pentose phosphates were derived more from glycolytic intermediates (e.g., increased [ $^{13}\text{C}_3$ ]-pentose phosphate;  $P < 0.0001$ ), than from the oxidative phase of the PPP (Figure 5E,F). Therefore, prior to refrigerated storage, G6PD-deficient RBCs are characterized by increased glycolysis and decreased ability to activate the oxidative phase of the PPP, the latter of which is important for producing NADPH.

### *Metabolomics during storage*

Principal component analysis (PCA) of metabolite differences in the glycolytic and PPP pathways (Figure 6A) comparing G6PD-normal and G6PD-deficient RBCs during 6-weeks of refrigerated storage revealed changes that evolve related to storage time and G6PD status (Figure 6B). There were no significant differences in glucose levels (Figure 6C) between G6PD-deficient and G6PD-normal RBCs; however, the levels of glucose 6-phosphate (G6P) and 6-phosphogluconolactone (6-PGL) exhibited a significant interaction with G6PD-status over time (Figures 6D,E), with median levels crossing each other at 2-4 weeks of storage. Similar to baseline, G6PD-deficient RBCs had increased glycolysis during storage, as compared to G6PD-normal RBCs, with significantly higher 2/3 PG and pyruvate levels

throughout (Figure 6I,J). The latter are products of the two ATP-producing reactions during glycolysis (Figure 6A), which are important for maintaining RBC ATP levels.

In contrast to results at baseline, at which point RBCs have not yet been exposed to the oxidant stress of storage, there are only minor differences between G6PD-deficient and G6PD-normal RBCs in lactate (Figure 6K) and ATP (Figure 6M) throughout storage. Nonetheless, similar to pyruvate, the pyruvate/lactate ratio (Figure 6L) is significantly higher in G6PD-deficient RBCs throughout storage. Of note, the reaction catalyzed by lactate dehydrogenase (LDH), converts pyruvate to lactate and consumes NADH in the process. However, higher oxidant stress in G6PD-deficient RBCs promotes the activation of NADH-dependent cytochrome-*b*<sub>5</sub> reductase, which would compete with LDH for free NADH. Our results suggest that G6PD-deficient RBCs limit the LDH-catalyzed reaction during storage to favor the activity of cytochrome-*b*<sub>5</sub> reductase, consistent with our previous observation that this enzyme is quantitatively more abundant in RBCs from G6PD-deficient subjects in comparison to controls.<sup>(23)</sup> Thus, G6PD-deficient RBCs have increased glycolysis as compared to G6PD-normal RBCs during storage, but they are also characterized by significantly higher pyruvate/lactate ratios.

#### *Differences in NADPH- and NADH-dependent reactions*

Consistent with the expected defect from G6PD deficiency, G6PD-deficient RBCs demonstrated a decrease in NADPH-dependent reactions and an increase in reactions that can produce NADPH (Figure 7). For example, reduction of GSSG to GSH is an NADPH-dependent reaction and, consistent with this, G6PD-deficient RBCs had significantly lower levels of GSH throughout storage (Figure 7A). Similarly, reducing biliverdin to bilirubin

consumes NADPH, and G6PD-deficient RBCs had significantly increased biliverdin throughout storage (Figure 7B), suggesting decreased activity in this pathway. Converting glucose to hexose sugar alcohols (e.g., sorbitol) is also an NADPH-dependent process that may be down-regulated in G6PD-deficient RBCs, as evidenced by significantly decreased hexose sugar alcohols throughout storage (Figure 7C). Furthermore, dihydroxynonene (DHN), which is produced from 4-hydroxynonenal (HNE) by an NADPH-consuming reaction, is significantly decreased in G6PD-deficient, as compared to G6PD-normal, RBCs during storage (Figure 7D).

Tricarboxylic acid (TCA) cycle enzymes are found in RBCs, along with their corresponding substrates and products.(34, 35) As examples, converting isocitrate to  $\alpha$ -ketoglutarate produces NADH, whereas converting malate to pyruvate via malic enzyme, which is present and active in RBCs,(36) produces NADPH. Consistent with the hypothesis that G6PD-deficient RBCs conserve NADH and increase NADPH production through non-G6PD catalyzed reactions, they have significantly higher levels of  $\alpha$ -ketoglutarate (Figure 7E) and pyruvate (Figure 6J) throughout storage, as compared to G6PD-normal RBCs. Taken together, although steady state measurements do not allow us to conclude directionality of the aforementioned pathways (i.e., we cannot conclude whether we are observing a decrease in the activation of the NADH/NADPH-dependent reaction or an increase in the NADH/NADPH-generating reaction), these results suggest that G6PD-deficient RBCs are characterized by alterations of several NADH- and NADPH-dependent pathways.

*Metabolites in non-oxidative phase of the PPP*

The non-oxidative phase of the PPP is connected to the oxidative phase, through 6-phosphogluconate (6PG) dehydrogenase, which produces ribulose 5-phosphate.(37) Glycolysis also contributes to the non-oxidative phase of the PPP through reversible interactions involving glyceraldehyde 3-phosphate (G3P) and fructose 6-phosphate (F6P) via the activity of transketolase and transaldolase (Figure 8A). At baseline, G6PD-deficient RBCs demonstrate increased non-oxidative PPP activity, as compared to G6PD-normal RBCs, evidenced by significantly increased concentrations of sedoheptulose phosphate (SP) ( $P=0.005$ ) and erythrose 4-phosphate (E4P) ( $P=0.004$ ) (Figure 8C,D). Furthermore, during storage there is a trend towards higher ribose phosphate (RP) and SP in G6PD-deficient RBCs (Figures 8B,C). Therefore, despite having a compromised oxidative phase of the PPP, G6PD-deficient RBCs maintain high levels of non-oxidative phase intermediates as compared to G6PD-normal RBCs. Data from the tracing experiments (Figure 5E,F) suggest that glycolysis provides much of the non-oxidative phase intermediates in G6PD-deficient RBCs. These results may also be consistent with inefficient nucleotide salvage, adversely affecting ATP levels, which decline to favor ATP breakdown into AMP and its oxidation to IMP and hypoxanthine.

#### *Pathways and metabolites correlating with RBC G6PD activity and PTR*

Metabolic markers predictive of PTR, particularly in the context of G6PD deficiency, have not yet been reported in the literature. To this end, we correlated our PTR data to discovery-mode metabolomics analyses of RBCs from G6PD-deficient and G6PD-normal subjects. Thus, PTR measurements were correlated to metabolomics data from the total study population, G6PD deficient subjects, or G6PD-normal subjects at baseline (Figure 9A-C,

respectively) or at the end of storage (i.e., Week 6; Figure 9D-F). Correlation analyses are reported in the form of circos plots, in which each metabolite or other variable (e.g., PTR or G6PD activity) is a node. Nodes are connected with an edge if the module of their linear correlation (Spearman) is above 0.4. Highlighted metabolites represent the most significant variables that correlate with either G6PD activity or PTR in the total population of subjects at baseline (Figure 9A) or at Week 6 (Figure 9D), only in the G6PD-deficient subjects at baseline (Figure 9B) or at Week 6 (Figure 9E), or in the G6PD-normal subjects at baseline (Figure 9C) or at Week 6 (Figure 9F). These results highlight a significant linkage between G6PD activity and PTR only when the total subject population is analyzed in a combined fashion. Top correlates to PTR and G6PD activity are identified, including metabolic intermediates of the PPP (e.g., ribose phosphate, erythrose phosphate), oxidation reactions and nucleotide salvage (e.g., hypoxanthine, IMP), transamination ( $\alpha$ -ketoglutarate, pyridoxal), lipid remodeling (several acyl-carnitines and octenoyl-carnitine), tryptophan metabolites (formyl-kynurenine), and conjugated bile acids (glyco- and taurocholate). Overall, metabolites involved in lipid remodeling, energy and redox metabolism, and nucleotide salvage had the best correlation with PTR (Figure 9G-L). For example, octenoyl-carnitine (Figure 9G), involved in lipid remodeling, and ribose phosphate (Figure 9H), in the non-oxidative phase of the PPP, and epiandrosterone, a steroid hormone, at baseline had some of the best correlations with PTR. In addition,  $\alpha$ -ketoglutarate (Figure 9J), produced by an NADH-generating reaction, hypoxanthine (Figure 9K), involved in purine salvage reactions, and octenoyl-carnitine (Figure 9L) measured after 6 weeks of storage had some of the strongest correlations with PTR.

## Discussion

Our results demonstrate that, after 40-42 days of storage, leukoreduced, G6PD-deficient RBCs have a decreased 24-hour PTR, as compared to G6PD-normal RBCs. These results with G6PD-normal subjects are similar to other published 24-hr PTR studies using AS-3 preserved units after 6 weeks of storage.(38) In contrast, if analyzed separately, RBC units from G6PD-deficient donors would not pass the current FDA criteria for clinical transfusion acceptability.(7) Chronically transfused patients may be adversely affected by non-optimal RBC transfusions, and patients with sickle cell disease, in particular, are exposed to a significant number of transfusions from G6PD-deficient donors (i.e., up to 12%).(25) Thus, the current results raise concerns regarding potential harm to patients transfused with G6PD-deficient RBCs.

Previous studies have demonstrated significantly increased reticulocytes and MCV in G6PD-deficient individuals with the A- and Mediterranean variants.(39-42) The results of studies comparing hemoglobin and hematocrit in deficient and normal subjects have varied, with studies specifically of blood donors showing no difference in hemoglobin and hematocrit between deficient and normal subjects,(23, 39) and others demonstrating lower hemoglobin and/or hematocrit in deficient subjects.(41, 42) In addition, decreased RBC count in G6PD-deficient subjects has been observed in studies with blood donors,(39) as well as other healthy individuals.(41, 42) The findings of increased reticulocyte count and decreased RBC count in G6PD-deficient subjects in the current study, in the setting of no differences in hemoglobin and hematocrit, suggest the presence of a sub-clinical, compensated hemolysis in deficient subjects at baseline.

The only previous study examining 24-hr PTR in G6PD-deficient and G6PD-normal RBCs also noted significant differences.(26) However, these non-leukoreduced RBC units were stored in either acid citrate dextrose-adenine (ACD-A) or citrate phosphate dextrose adenine (CPDA)-1 solutions and, under both conditions, G6PD-deficient RBCs exhibited lower 24-hr PTRs (67.2% vs 74.4% in ACD-A and 58.1% vs 72% in CPDA-1). At that time, the criteria for the suitability of stored RBCs included an average 24-hr PTR greater than 70%. Similar to our results, a greater proportion of the G6PD-deficient RBC units failed this criterion. In addition, they found no correlation between G6PD enzyme activity and PTR within a given G6PD-status group (i.e., separately assessing the correlation between PTR and enzyme activity for G6PD-normal RBCs and G6PD-deficient RBCs; Figure 2D).(26) We also observed significant variability in the PTR among subjects with G6PD-deficiency (SD=8.4%), suggesting that there are other factors (e.g., genetic or environmental) that affect storage quality, independent of G6PD activity. Notably, the storage solution affected the quality of the G6PD-deficient, but not G6PD-normal, RBCs. Thus, although PTR for G6PD-deficient RBCs stored in CPDA-1 (i.e., 58.1%) was lower than in ACD-A (i.e., 67.2%), there was no significant difference in PTR for G6PD-normal RBCs stored in either preservative.(26) Because the type of storage solution affects RBC metabolism,(9) these results suggest that G6PD-deficient RBCs may vary in quality based on storage solution composition.

We found no significant differences in storage hemolysis *in vitro* (Figure 3A), another important FDA criterion for assessing RBC quality, between G6PD-deficient and G6PD-normal RBCs. In addition, prior studies comparing G6PD status in various additive solutions (e.g., ACD-A, CPDA-1,(26) SAGM,(23)) or following irradiation,(43) did not reveal differences in storage hemolysis *in vitro*. Although the determinants of *in vitro* hemolysis during refrigerated

storage are not well understood, factors such as sex, age, ethnicity,(44) and other unknown heritable traits,(12) may be important.

G6PD-deficient RBCs maintained lower methemoglobin levels during storage (Figure 3B). Methemoglobin, which contains oxidized iron ( $\text{Fe}^{3+}$ ), releases oxygen poorly to tissues. Thus, reduction of methemoglobin is important for maintaining optimal RBC function; to this end, cytochrome- $b_5$  reductase uses NADH for this purpose. Stored G6PD-deficient RBCs have significantly increased cytochrome- $b_5$  reductase levels as compared to G6PD-normal RBCs.(23) During glycolysis, NADH is produced by GAPDH when converting G3P to BPG. Our data suggest that G6PD-deficient RBCs maximize NADH production, as evidenced by significant decreases in glyceraldehyde 3-phosphate and significant increases in BPG, the substrate and product of GAPDH, respectively (Figure 6G,H and Figure 4B). G6PD-deficient RBCs also appear to preserve NADH by limiting the conversion of pyruvate to lactate, an NADH-consuming reaction catalyzed by LDH, as evidenced by the significantly increased pyruvate/lactate ratios throughout storage (Figure 6J-L). Thus, G6PD-deficient RBCs demonstrate alterations in glycolysis that enable them to maintain NADH levels throughout storage. Although the reduced methemoglobin levels observed in refrigerator-stored G6PD-deficient RBCs may be advantageous upon transfusion from an oxygen delivery perspective, it is likely that the increased clearance observed with G6PD-deficient RBCs, overshadows this relatively small difference in methemoglobin levels.

In the current and prior studies,(23, 45) G6PD-deficient RBCs, whether fresh or stored, demonstrated increased glycolysis. Since G6P is at the bifurcation point of the PPP and glycolysis, more G6P should be available for glycolysis in G6PD-deficient RBCs due to their defect in the oxidative branch of the PPP. Important products of glycolysis include ATP and

NADH. Therefore, increased glycolysis is expected to allow G6PD-deficient RBCs to maintain ATP levels. Consistent with this, fresh G6PD-deficient RBCs had significantly increased ATP as compared to G6PD-normal RBCs (Figure 4G). Furthermore, G6PD-deficient RBCs maintained ATP at levels similar to G6PD-normal RBCs during storage (Figure 6M).

The PPP contains oxidative and non-oxidative branches. The oxidative branch results in oxidation, catalyzed by G6PD, of G6P to 6-PGL, followed by decarboxylation, catalyzed by 6PG dehydrogenase, to produce ribulose-5-phosphate. Tracing experiments with [1,2,3-<sup>13</sup>C<sub>3</sub>] glucose, in the presence or absence of the PPP-stimulating agent methylene blue, demonstrate that fresh G6PD-normal, but not G6PD-deficient, RBCs activate the oxidative phase of the PPP (Figure 5). However, following 6-weeks of storage, both G6PD-deficient and G6PD-normal RBCs were unable to activate the oxidative branch of the PPP following methylene blue treatment, suggesting that this pathway ultimately degrades during storage, even in G6PD-normal donors as has been previously observed.(46)

G6PD-deficiency decreases the ability of RBCs to produce NADPH.(16) As a possible compensatory mechanism for maintaining NADPH, G6PD-deficient RBCs increased activity in alternative reactions and pathways that generate NADPH. Thus, because of the expected defect in NADPH production by the oxidative branch of the PPP due to G6PD deficiency (Figure 5), G6PD-deficient RBCs have storage-induced decreases in GSH, hexose sugar alcohol, and DHN, which are produced by NADPH-consuming reactions (Figure 7). G6PD-deficient RBCs had significantly lower levels of GSH throughout storage, likely due to a combination of decreased GSSG reduction to GSH (a NADPH-dependent reaction), export of GSSG from RBCs,(47) and increased protein glutathionylation in response to oxidative stress. In addition, biliverdin was significantly increased in G6PD-deficient RBCs during storage,

consistent with decreased NADPH-driven conversion to bilirubin. G6PD-deficient RBCs also had significant increases in TCA cycle intermediates, such as succinate, fumarate, and malate (Figure 7). The conversion of malate to pyruvate is an NADPH-producing reaction, raising the possibility that the increasing pyruvate levels during storage in G6PD-deficient RBCs (Figure 6) are not only due to conversion from PEP during glycolysis, but may also be a byproduct of NADPH formation from malate. Therefore, G6PD-deficient RBCs may compensate for their decreased ability to produce NADPH through the PPP by increasing activity in alternative pathways that are independent of G6PD.

The strongest correlations to PTR were metabolites related to pathways that produce NADH (e.g.,  $\alpha$ -ketoglutarate), salvage nucleotides (e.g., hypoxanthine and IMP), are intermediates of the PPP (e.g., erythrose phosphate and ribose phosphate), are involved in lipid remodeling (e.g., octenoyl-carnitine), that maintain glutathione homeostasis (e.g., glutathione disulfide and S-glutathionylcysteine), and a steroid hormone (e.g., epiandrosterone; Figure 9). Consistent with seminal studies on RBC metabolism and PTR, maintenance of energy metabolism and, in particular, ATP levels were positively correlated with PTR.(46) Our results further confirm and expand on the negative correlation of ATP breakdown and oxidant stress-induced deamination (i.e., hypoxanthine and IMP) to PTR.(48, 49) Consistently, the levels of reduced glutathione (GSH), a critically-important antioxidant, positively correlated with PTR, in keeping with classic studies.(46) Decreases in S-glutathionylcysteine and GSH during storage are more marked in G6PD-deficient RBCs, consistent with likely increases in cysteine glutathionylation as a compensatory protection against oxidative stress in G6PD-deficient subjects.(50) Finally, the correlation of epiandrosterone, a steroid hormone shown to affect glucose metabolism and PPP activity *in*

*vitro*,<sup>(51)</sup> and PTR from samples at baseline is interesting given the potential link between sex hormones and RBC storage quality.<sup>(44, 52, 53)</sup>

The current study has some limitations. For example, the primary outcome is the 24-hr PTR, as opposed to other markers of RBC destruction, such as indirect bilirubin or iron parameters, which may correlate better with hemolysis *in vivo*.<sup>(54)</sup> This primary outcome was chosen *a priori* because of the “precautionary principle;” that is, the entire unit was not transfused in this study because we wished to prevent G6PD-deficient donors from experiencing severe hemolysis in the event that storage of their RBCs led to severe damage. In addition, although PTR was quantified in this study, RBC lifespan was not evaluated beyond the 24-hr time-point. Nonetheless, prior studies showed no differences in the post-transfusion lifespan of G6PD-deficient and G6PD-normal RBCs.<sup>(26)</sup> Also, only the extreme of storage was examined (i.e., 6 weeks); thus, future studies could examine effects at shorter storage intervals. Furthermore, in a study using autologous recipients, one could not determine whether protective compensatory mechanisms in the plasma of G6PD-deficient subjects could compensate for their poor redox status, as previously reported,<sup>(55)</sup> or whether the difference in PTR is due to an intrinsic defect of G6PD-deficient RBCs as opposed to extrinsic effects of G6PD-deficiency on RBC clearance. It is also possible that plasma factors in G6PD-normal recipients could improve the survival of G6PD-deficient RBCs;<sup>(55)</sup> however, this effect would need to be studied in the context of allogeneic transfusions, which were not the focus of this autologous PTR study in which the primary outcome measure was the FDA gold-standard test. Also, the chromium labeling efficiency and elution rate may be different in G6PD-deficient, as compared to G6PD-normal, RBCs. However, the chromium labeling efficiency in damaged RBCs is minimally affected,<sup>(56)</sup> and the variability seen in chromium elution rates among

patients with hematologic diseases are not sufficient to explain the overall differences in PTR observed in G6PD-deficient donors.(57) In addition, although there was a statistically significant decrease in the PTR for G6PD-deficient RBCs, this study was performed in healthy volunteers; thus, it remains unknown if this PTR difference would be greater in transfused patients, such as those with sickle cell disease, who experience increased oxidative stress at baseline.(58) For example, chronically transfused pediatric patients with sickle cell disease have poorer suppression of reticulocytosis and higher hemoglobin S levels between transfusion episodes when receiving G6PD-deficient donor RBCs.(28) It is also possible that results would vary if donor RBCs were stored in different additive solutions. Thus, all RBC units in this study were stored in AS-3; however, prior studies found a significant difference in PTR when G6PD-deficient RBCs were stored in ACD-A (67.2%) or CPDA (58.1%).(26) Finally, some of our correlative results are limited by an appreciation that the lowest PTRs were observed with G6PD-deficient RBCs. As such, metabolites correlating with G6PD activity *per se* (or not) also significantly correlated with PTR. Although further studies in larger cohorts are necessary to validate the present findings, there is growing interest in the potential effects of RBC donor genetics on transfusion outcomes.(59)

Experts in the field of transfusion medicine are focusing significant effort on determining the genetic factors underlying the observed donor variability in RBC storage.(60-62) The current study provides unequivocal evidence that one such genetic factor, G6PD-deficiency, significantly decreases 24-hr PTR after 6-weeks of storage. In addition, RBC units from donors with G6PD-deficiency, if studied as a group, would not meet the current FDA criterion for transfusion quality. The clinical impact of this finding for all transfused patients, and for chronically transfused patients with sickle cell disease, in particular,(25) should be further

investigated. In addition, understanding the metabolic mechanism(s) by which G6PD deficiency impairs storage quality will yield valuable information for not only improving the storage of G6PD-deficient RBCs, but also for improving RBC transfusion efficacy overall.

## Methods

### *Participant recruitment*

Male volunteers were recruited using flyers, person-to-person communication, and email, between November 2012 and August 2017. Screening was limited to males because G6PD deficiency is X-linked; thus, heterozygous females are not expected to have the same severity of enzyme deficiency as hemizygous males, and homozygous females are rare in the population.<sup>(63)</sup> Furthermore, advertisements focused on ethnicities known to have a higher prevalence of G6PD deficiency, which included African, Mediterranean, Middle Eastern, Hispanic/Latino, and Asian origin. Inclusion criteria were male gender, weight greater than 110 pounds, and hemoglobin greater than 11.5 g/dL. Participants were also screened for microcytosis (Sysmex XN9000, Sysmex; Lincolnshire, IL) and for hemoglobin variants (Bio-Rad Variant II; Bio-Rad, Hercules, CA). G6PD activity was measured by a CLIA-certified reference laboratory (ARUP Laboratories; Salt Lake City, Utah). All 13 exons of the *G6PD* gene of G6PD-deficient volunteers were analyzed by next-generation sequencing in the CLIA-certified Personalized Genomics Laboratory at Columbia University Irving Medical Center, New York, NY to identify the specific G6PD variant present.<sup>(64)</sup>

### *Blood donation and storage*

Following screening and confirming G6PD activity, 10 G6PD-deficient and 30 G6PD-normal males donated one unit of whole blood at the New York Blood Center (New York, NY), each of which was processed into packed RBCs, leukoreduced, and stored in additive solution (AS)-3. RBC units were refrigerator stored for up to 42 days under standard blood banking conditions. Using sterile docking procedures, 25 mL aliquots were removed during each week

of storage (i.e., weeks 1, 2, 3, 4, 5, 6) for *in vitro* analyses. Each 25 mL aliquot was divided as follows: 1) 3 mL for blood gas analysis, 2) 7 mL distributed into 250  $\mu$ L aliquots and frozen in liquid nitrogen, and 3) 15 mL centrifuged at 3,900 x *g* for 7 minutes at 4°C. The supernatant of the latter was transferred to 1.5 mL microcentrifuge tubes and the remaining RBCs were centrifuged again at 3,900 x *g* for 7 minutes at 4°C. Supernatant was again transferred to 1.5 mL microcentrifuge tubes and all supernatants were centrifuged at 12,600 x *g* for 6 minutes. All separated RBCs and supernatants were separately distributed into 1.5 mL microcentrifuge tubes in 250  $\mu$ L aliquots and frozen in liquid nitrogen. All frozen samples were stored at -80°C until metabolomics analysis. At week 5, an additional sample was submitted for aerobic and anaerobic blood culture to confirm the absence of bacterial contamination during storage.

#### *Conventional measurements in vitro*

At each week of storage, pH, methemoglobin, sodium, glucose, and lactate were measured using a clinically-validated ABL 800 Flex Blood Gas Analyzer (Radiometer; Brea, CA). Hemoglobin and hematocrit were measured on a clinically-validated Sysmex XN9000 (Sysmex; Lincolnshire, IL). Supernatant hemoglobin was measured weekly, as follows: supernatant was obtained by centrifuging 500  $\mu$ L of RBC concentrate at 2,000 x *g* for 10 minutes and hemoglobin quantified using the Drabkin method; the hemolysis rate was then calculated, as previously described.<sup>(65)</sup>

#### *Metabolomics*

At study completion, samples were shipped on dry ice to the University of Colorado Denver – Anschutz Medical Campus, where they were either untreated or incubated with 100

$\mu\text{M}$  methylene blue for 1h at 37°C in the presence of 5 mM [1,2,3- $^{13}\text{C}_3$ ] glucose. Samples were then extracted with a mixture of ice-cold methanol, acetonitrile, and water (5:3:2 v/v/v, respectively) at a 1:10 ratio for RBCs (e.g., 15  $\mu\text{L}$  of sample with 135  $\mu\text{L}$  of extraction solvent) or a 1:25 ratio for RBC supernatant. Extractions were performed by vigorous vortexing for 30 min at 4°C; insoluble materials were then pelleted by centrifugation for 10 min at 4°C; centrifugation speeds were 18,000  $\times g$  for RBC extractions and 12,000  $\times g$  for RBC supernatant extractions. Clarified extraction supernatants were analyzed by ultra-high-pressure liquid chromatography coupled online to high-resolution mass spectrometry (UHPLC-MS) using a Thermo Vanquish UHPLC coupled to a Thermo Q Exactive MS. Samples were randomized and run in positive and negative ion modes (separate runs). Injection volumes were 10  $\mu\text{L}$  for RBC samples and 20  $\mu\text{L}$  for RBC supernatant samples. UHPLC phases were water (A) and acetonitrile (B) supplemented with 0.1% formic acid for positive mode runs and 1 mM ammonium acetate for negative mode runs. Metabolites were separated on a Kinetex C18 column (2.1  $\times$  150 mm, 1.7  $\mu\text{m}$ , Phenomenex; Torrance, CA), equipped with a guard column, using a 5 minute gradient under the following conditions: flow rate 0.45 mL/min; column temperature 45°C; sample compartment temperature 7°C; solvent gradient: 0-0.5 min 5% B, 0.5-1.1 min 5-95% B, 1.1-2.75 min hold at 95% B, 2.75-3 min 95-5% B, 3-5 min hold at 5% B. (66) The mass spectrometer was operated in full MS mode at a resolution of 70,000, scan range 65-900 m/z, maximum injection time 200 ms, microscans 2, automatic gain control (AGC)  $3 \times 10^6$  ions, electrospray source voltage 4.0 kV, capillary temperature 320°C, and sheath gas 45, auxiliary gas 15, and sweep gas 0 (all nitrogen). Raw data files were converted to mzXML format using MassMatrix (Case Western Reserve University; Cleveland, OH) and analyzed using Maven (Princeton University; Princeton, NJ). Hierarchical clustering analysis

(HCA) and partial least squares-discriminant analysis (PLS-DA) were performed with the MetaboAnalyst 4.0 and GENE E (Princeton, MA) freeware. Instrument stability and quality control were assessed using replicate injections of a technical mixture every 15 runs, as previously described.(67, 68)

### *Tracing experiments with [1,2,3-<sup>13</sup>C<sub>3</sub>] glucose*

Tracing experiments with [1,2,3-<sup>13</sup>C<sub>3</sub>] glucose were performed as previously described,(22) with fresh RBCs collected directly from donors (fresh) or RBCs stored for 6 weeks (stored).

### *24-Hour PTR studies*

After 40-42 days of storage (i.e., week 6), 24-hr PTR studies were performed, as previously described.(69) Briefly, 25 mL of RBCs were labeled with 20 µCi of sodium chromate (Mallinckrodt Pharmaceuticals; Bedminster, NJ), followed by infusion of the labeled RBCs over 1 minute. Blood samples were collected prior to infusion, and at 5, 7.5, 10, 12.5, 15, 30, 60, and 120 minutes post-infusion; a final sample was obtained at 24 hours post-infusion. Radioactivity and hemoglobin were measured in each sample on a Gamma Counter (Packard Cobra II Auto-Gamma, Perkin Elmer; Waltham, MA) and a Sysmex XN9000 (Sysmex; Lincolnshire, IL) analyzer, respectively. The 24-hr PTR was then calculated using all timed blood draws for estimating the 51-Chromium per gram hemoglobin circulating at time-zero.(70)

### *Statistics*

The primary outcome difference in 24-hour PTR between G6PD-deficient and G6PD-normal subjects was calculated using an independent two-sided student's t-test. Historical studies suggested that the difference in RBC recovery would be relatively large (e.g.,  $72.2\% \pm 9.18\%$  and  $58.1\% \pm 9.81\%$  in G6PD-normal and G6PD-deficient subjects, respectively).(26) However, we expected a smaller difference and assumed a 6% SD for our primary outcome measure based on studies using modern storage solutions.(7) Thus, to provide sufficient power to explore whether specific *in vitro* storage metabolomics parameters could predict PTR *in vivo*, we recruited 10 G6PD-deficient subjects and 30 G6PD-normal controls. Using an independent student's t-test, this provided >78% power to detect a 6% absolute difference in PTR. Secondary analyses of differences in metabolite levels over time were performed using two-way repeated-measures ANOVA and Sidak's multiple comparisons test (or mixed-effects model if missing values) using Prism, version 8 (GraphPad Software, Inc.; San Diego, California), or MetaboAnalyst, version 4.0. Significance of main effects was determined using two-factor time-series analysis in MetaboAnalyst with a false discovery rate (FDR) of 0.10. Subsequently, Prism was used to graph the significant findings and final p-values determined using two-way repeated-measures ANOVA. In addition, metabolic correlations (Spearman) were calculated and plotted as circos plots through MetaboScape, version 4.0 (Bruker) for the network building software Cytoscape, version 3.7 (National Resource for Network Biology). In this analysis, metabolites are plotted as nodes and connected with an edge if the module of their correlation (Spearman) is higher than 0.4. Highlighted nodes represent top ranking metabolites by the module of their linear Spearman correlations (filtered by  $FDR < 0.10$ ) for each analysis (total sample, G6PD-deficient or G6PD-normal groups, either at baseline or after 6 weeks of storage).

### *Study approval*

The study was conducted according to the Declaration of Helsinki and in accordance with good clinical practice guidelines. The Columbia University (Protocol AAAJ6862) and New York Blood Center (Protocol 401165) Institutional Review Boards approved this study. All research participants were provided with written, informed consent prior to study participation.

## **Author contributions**

ROF, EAH, and SLS designed, and ROF led the clinical trial. FR assisted with data collection. RY, EC, AS, and CD assisted with the PTR studies. EAH, AD, and ROF analyzed the clinical data. DK, YG, and BHS assisted with blood donation procedures. AE and JS assisted with blood banking processes. SG, JAR, TN, and AD performed metabolomics analyses. ROF and AD drafted the first version of the manuscript. All authors edited and approved the final manuscript.

## **Acknowledgements**

<b>Mean Reticulocyte %* (SD)</b>	1.4 (0.3)	2.2 (0.4)	<0.001
<b>Mean G6PD Activity U/g Hb (SD)</b>	11.2 (1.0)	2.4 (0.9)	<0.001

\*Reticulocyte data not available for 2 G6PD-deficient and 3 G6PD-normal subjects

Abbreviations: Mean corpuscular hemoglobin (MCH); mean corpuscular hemoglobin concentration (MCHC); red blood cell (RBC); mean corpuscular volume (MCV); and red blood cell distribution width (RDW).

**Figure 1. CONSORT Diagram.** Number of subjects who were screened, excluded, dropped out, and completed the study.

**Figure 2. G6PD-deficiency reduces 24-hour PTR. (A)** The 51-chromium PTRs for G6PD-normal (N=27) and G6PD-deficient (N=10) subjects are shown. The dotted gray line denotes the FDA criterion for acceptability (i.e., at outdate, on average >75% of transfused RBCs should still be circulating for 24 hours). **(B)** The 51-chromium PTRs for G6PD-normal (N=6) and G6PD-deficient (N=7) subjects of African origin and **(C)** non-African origin are shown (N=21 and 3 for G6PD-normal and G6PD-deficient, respectively). Means and standard deviation are shown. Statistical significance calculated using an unpaired t-test. \* $P < 0.05$ , \*\*\* $P < 0.001$ . **(D)** Correlation between G6PD enzyme activity and PTR is shown. Results of linear regression for all subjects (N=37) is shown with the 95% CI in dashed gray lines ( $R^2 = 0.27$ ;  $P = 0.001$ ). Within-group results for G6PD-deficient (red) and G6PD-normal (blue) volunteers are depicted along with the results of the corresponding linear regression (red and blue lines, respectively), which are not statistically significant by Pearson correlation. The unfilled red circle represents the single subject with the Mediterranean variant.

**Figure 3. Standard *in vitro* measures of RBC units throughout storage.** (A) Spontaneous hemolysis, (B) methemoglobin, (C) lactate, (D) pH, (E) glucose, and (F) sodium were measured in aliquots obtained from each unit at the designated storage time. G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) are represented. Means and standard deviations are shown. Statistical significance was calculated using two-way repeated-measures ANOVA with Sidak's multiple comparisons test; \* $P < 0.05$ . Thick dotted red line denotes the FDA criterion for the allowable spontaneous hemolysis rate during storage.

● Normal  
● Deficient  
○ Mediterranean variant

**Figure 4. Differences in glycolysis between G6PD-deficient and G6PD-normal RBCs at baseline. (A)** Schematic of the glycolytic pathway. The levels of glycolytic intermediates were measured in RBCs collected directly from volunteers and measured prior to storage. **(B)** Bisphosphoglycerate, **(C)** 2/3 Phosphoglycerate, **(D)** Phosphoenolpyruvate, **(E)** Pyruvate, **(F)** Lactate, and **(G)** ATP in G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) RBCs are shown. Median with interquartile range represented. Unfilled red circles represent the single subject with the Mediterranean variant. Statistical significance was assessed by the Mann Whitney U test; \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$ . AU = arbitrary units.

**Figure 5. Defective activation of the PPP in response to methylene blue stimulation in G6PD-deficient RBCs.** (A) Fresh (unstored) or 6-week stored RBC lysates were incubated with [1,2,3-<sup>13</sup>C<sub>3</sub>] glucose and then treated with methylene blue to stimulate the oxidative phase of the PPP. The presence of 3-carbon moieties was measured and isotopologues compared. <sup>13</sup>C<sub>2</sub> 3-carbon species indicate metabolism by the PPP and <sup>13</sup>C<sub>3</sub> species indicate metabolism by glycolysis. (B) Glycolytic pathway activity, as measured by [<sup>13</sup>C<sub>3</sub>]-glucose phosphate levels, (C) PPP pathway activity, as measured by [<sup>13</sup>C<sub>2</sub>]-lactate levels, (D) the ratio of [<sup>13</sup>C<sub>2</sub>]-lactate levels/[<sup>13</sup>C<sub>3</sub>]-glucose phosphate levels indicating the ratio of PPP/glycolysis, and (E) [<sup>13</sup>C<sub>3</sub>]-pentose phosphate demonstrating the pentose phosphate derived from glycolysis pathway activity in fresh and stored (as labeled) G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) RBCs, with either vehicle (circles) or methylene blue treatment (squares), were all determined. Medians with interquartile ranges are represented. Unfilled symbols represent the single subject with the Mediterranean variant. Statistical significance calculated using two-way ANOVA with Sidak's multiple comparisons test; \**P*<0.05. (F) Schematic demonstrating that pentose phosphates are derived more from the contributions of glycolytic intermediates, rather than the oxidative phase of the PPP, in G6PD-deficient RBCs. AU = arbitrary units.

○ Vehicle  
□ Methylene Blue

**Figure 6. G6PD-deficient RBCs are characterized by altered glycolysis and PPP activity during storage.** (A) Schematic of glycolysis with branching to the PPP. Metabolite levels were measured in RBCs during weeks 1 to 6 of refrigerated storage. (B) PCA of the metabolites throughout storage. (C) Glucose, (D) Glucose-6-phosphate, (E) 6-phosphogluconolactone, (F) Fructose 1,6 bisphosphate, (G) Glyceraldehyde-3-phosphate, (H) Bisphosphoglycerate, (I) 2/3-Phosphoglycerate, (J) Pyruvate, (K) Lactate, (L) Pyruvate/Lactate ratio, (M) ATP. Medians with interquartile ranges are shown. G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) are represented. The dotted red line with the unfilled circle represents the single subject with the Mediterranean variant. Statistical significance was calculated using two-way repeated-measures ANOVA with Sidak's multiple comparisons test; \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$ . Significance for the effect of storage time and the interaction between G6PD status and time are as labeled, or not significant if not shown. Significant time points are shown and significant differences between G6PD-deficient and G6PD-normal subjects are denoted with a bracket to the right of the curves. When the interaction term was significant, the significance of the main effects was assessed in MetaboAnalyst. AU = arbitrary units.

**Figure 7. NADPH-dependent/generating metabolic pathways affected by G6PD deficiency in stored RBCs.** Metabolite levels were measured in RBCs during weeks 1 to 6 of refrigerated storage. Schematic of the NADPH-dependent/generating pathway shown with graphs of relevant metabolites throughout storage to the right in each figure panel. **(A)** Reduction of oxidized glutathione (GSSG) to reduced glutathione (GSH) and glutathionylation of cysteine residues (S-glutathionyl-Cys), **(B)** conversion of biliverdin to bilirubin, **(C)** conversion of glucose to hexose sugar alcohol, **(D)** conversion of 4-hydroxynonenal (HNE) to dihydroxynonene (DHN), and **(E)** conversion of malate to pyruvate. Medians with interquartile ranges are shown. G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) are represented. The dotted red lines with the unfilled circles represent the single subject with the Mediterranean variant. Statistical significance was calculated using two-way repeated-measures ANOVA with Sidak's multiple comparisons test; \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$ . Significance for the effect of storage time and the interaction between G6PD status and time are as labeled, or not significant if not shown. Significant time points are shown and significant differences between G6PD-deficient and G6PD-normal subjects are denoted with a bracket to the right of the curves. When the interaction term was significant, the significance of the main effects was assessed in MetaboAnalyst. AU = arbitrary units.

**Figure 8. The Non-Oxidative Phase of the PPP is maintained in G6PD-deficient RBCs.**

**(A)** Schematic of the non-oxidative phase of the PPP and its connection with glycolysis in gray. Metabolite levels were measured in RBCs before storage (i.e., fresh) and during weeks 1 to 6 of refrigerated storage. The metabolites **(B)** ribose phosphate, **(C)** sedoheptulose phosphate, and **(D)** erythrose 4-phosphate are shown. Medians with interquartile ranges are shown. G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) are represented. The dotted red lines with unfilled red circles represent the single subject with the Mediterranean variant. Statistical significance was calculated by Mann Whitney U test (fresh) or by two-way repeated-measures ANOVA with Sidak's multiple comparisons test (storage); \*\* $P < 0.01$ , \*\*\*\* $P < 0.0001$ . Significance for the effect of time and the interaction between G6PD status and time are as labeled, or not significant if not shown. Significant differences between G6PD-deficient and G6PD-normal subjects are denoted with a bracket to the right of the curves. AU = arbitrary units.

A

**Figure 9. Metabolic alterations at baseline and end of storage in G6PD-deficient RBCs correlate with G6PD activity and PTR.** Circos plots of metabolic correlates to PTR and G6PD activity in the total population of subjects at baseline (**A**) or after 6 weeks of storage (**D**), in only G6PD-deficient subjects at baseline (**B**) or Week 6 (**E**), or only G6PD-normal subjects at baseline (**C**) or Week 6 (**F**). Metabolites are represented as nodes and connected by an edge if their linear correlation (Spearman) is higher than 0.4. Highlighted nodes represent the most significant correlates (Spearman, FDR adjusted p-values < 0.05) with PTR (black spheres) or G6PD activity (blue spheres). The correlation of baseline levels of octenoyl-carnitine (**G**), ribose phosphate (**H**), and epiandrosterone (**I**); and Week 6 levels of  $\alpha$ -ketoglutarate (**J**), hypoxanthine (**K**), and octenoyl-carnitine (**L**) in the total subject population, or limited to only G6PD-deficient or G6PD-normal subjects, respectively. \* $P$ <0.05, \*\* $P$ <0.01. G6PD-normal (blue; N=27) and G6PD-deficient (red; N=10) subjects are represented. The unfilled red circle represents the single subject with the Mediterranean variant. AU = arbitrary units.
