1 Abstract

2 NKT cells are innate-like T cells, recruited to the skin during viral infection, yet their contributions 3 to long-term immune memory to viruses are unclear. We identified granzyme K, a product made by cytotoxic 4 cells including NKT cells, is linked to induction of Th1-associated antibodies during primary dengue virus 5 (DENV) infection in humans. We examined the role of NKT cells in vivo using DENV-infected mice lacking 6 CD1d-dependent (CD1d^{dep}) NKT cells. In CD1d-KO mice, Th1-polarized immunity and infection resolution 7 were impaired, which was dependent on intrinsic NKT cell production of IFN- γ , since it was restored by 8 adoptive transfer of WT but not IFN-y-KO NKT cells. Furthermore, NKT cell deficiency triggered immune 9 bias, resulting in higher levels of Th2-associated IgG1 than Th1-associated IgG2a, which failed to protect 10 against a homologous DENV re-challenge and promoted antibody-dependent enhanced disease during 11 secondary heterologous infections. Similarly, Th2-immunity, typified by a higher IgG4:IgG3 ratio, was 12 associated with worsened human disease severity during secondary infections. Thus, CD1ddep NKT cells 13 establish Th1 polarity during the early innate response to DENV, which promotes infection resolution, 14 memory formation and long-term protection from secondary homologous and heterologous infections in 15 mice, with consistent associations observed in humans. These observations illustrate how early innate 16 immune responses during primary infections can influence secondary infection outcomes.

17

18 Introduction

19

20 Viral pathogens such as flaviviruses, coronaviruses and influenza viruses pose unique challenges 21 for adaptive immune responses because of the existence of many serotypes and/or frequent emergence 22 of new variants. Because of antigenic similarities between the species within these families, re-exposure to 23 a heterotypic viral challenge can elicit an adaptive immune response that is partially protective or, 24 alternatively, potentially enhancing for infection or pathogenesis(1). However, early innate immune events 25 are understood to both limit primary viral infection and influence downstream adaptive responses, but how 26 innate immune responses influence memory recall and protection in secondary infections is hardly 27 understood.

28 One virus for which pre-existing heterologous immunity can be problematic is dengue virus (DENV). 29 an arboviral pathogen with a substantial worldwide burden as the most common vector-borne viral 30 disease(2, 3). Having 4 serotypes and a multitude of closely related viruses in the same family, DENV 31 poses a unique public health challenge with respect to its high frequency of reinfection or re-exposure to 32 antigenically similar heterotypic infections in the same host, which can alter the disease course(4). Immune 33 memory in DENV infections is associated with strong and long-lasting serotype-specific protection. 34 However, secondary infections with a heterologous serotype of DENV are associated with a risk of 35 heightened disease severity(4). It is thought that this risk of severity is dependent primarily on antibody 36 concentration and specificity(5), where non-neutralizing antibodies can lead to antibody-dependent 37 enhancement (ADE) of infection(5), but the immune factors that promote the development of infection-38 enhancing antibodies are unclear.

39 DENV infection begins when the virus is subcutaneously injected into skin by mosquito bite. Viral 40 particles deposited in the skin initially infect local monocytes and dendritic cells (DCs) and activate resident 41 innate immune sentinel cells, such as mast cells, which prompt cellular recruitment (4, 6-9). Although DENV 42 is able to disseminate via lymphatic vessels to draining lymph nodes (dLNs) and establish replication in 43 various target organs, this early innate immune response is key for limiting infection (9, 10). Early clearance 44 of DENV from the skin is promoted by an innate response involving innate-like T cells such as γδT cells 45 and NK1.1⁺ cells (6, 11). Both natural killer (NK) and natural killer T (NKT) cells are recruited to the skin, 46 with enrichment for NKT cells (6), but it is not known which subsets of NK1.1⁺ T cells are consequential to 47 DENV infection clearance and if they influence long-term immune memory.

48 NKT cells display a hybrid transcriptional phenotype of both NK and T cells (12, 13) and can rapidly 49 produce a variety of cytokines and/or acquire cytotoxic functionality upon T cell receptor (TCR) activation 50 (14, 15). Currently, in mice, NKT cells are classified into three main subsets: CD1d-dependent (CD1d^{dep}) 51 Type-I, CD1d-dependent Type-II, and CD1d-independent (CD1d^{ind}) NKT-like cells (15), which differ in their 52 abilities recognize specific antigens(12, 14, 16, 17), as well as their cytokine secretion profiles and cytotoxic 53 capabilities(17-20). In humans as well, although there are differences in TCR utilization and in vivo 54 distribution, there are also invariant CD1d-dependent and -independent NKT cells(17). NKT cells are 55 strongly linked with antiviral immunity. For example, NKT markers were detected on a large percentage of 56 virus-specific CD8⁺ and CD4⁺ T cells during lymphocytic choriomeningitis virus infection in mice (21). NKT 57 cell deficiency also led to impaired clearance of herpes simplex and hepatitis B virus infections in mice (22, 58 23), and NKT cells were shown to be responsible for induction of virus-specific CTL responses against 59 respiratory syncytial and influenza viruses (24, 25). While there is evidence that NKT cells can influence 60 other immune cells through regulating cytokine secretion or interaction with antigen presenting cells (APCs) 61 (26), the specific contributions of NKT cells (independent of NK cells) to immunity and clearance of 62 cutaneous virus infection are not fully understood. Furthermore, their influence on adaptive immunity and 63 long-term memory responses, and especially those independent of their ability to, themselves, convert to 64 memory phenotypes, have not been adequately explored.

65 Here, we identified a link between biomarkers of NKT cell activation and a Th1-polarized immune 66 response in primary dengue patients, involving both serum cytokines and antibody subclasses. Using mice 67 deficient in CD1d^{dep} NKT cells, we disentangled the contributions of NKT cells to innate clearance of acute 68 infection from their influence on adaptive responses, and learned that NKT cell driven adaptive immunity 69 can regulate secondary infection outcomes. We observed that NKT-dependent Th1-immune polarization in 70 mice led to protection during secondary homologous and heterologous infections, in a mechanism 71 dependent on the intrinsic production of IFN-y by NKT cells. As in mice, severe disease in secondary dengue patients was strongly associated with a Th2 characteristic profile of pre-existing antibodies. These 72 73 results support a dual role for CD1d^{dep} NKT cells in DENV infection resolution dependent on Th1-associated 74 immune responses, as well as long-term antibody mediated protection against re-infection.

75

76 Results

77 NKT cell activity primes for Th1 immune bias during primary human dengue infections

We first questioned if immune signatures of cytotoxic lymphocyte activation could be a predictor of efficient induction of Th1-associated immune responses in DENV-infected humans. Human dengueconfirmed patients from a hospitalized pediatric cohort were longitudinally sampled at days 1-3 and days 6-7 post fever onset, representing time points of acute infection (i.e. at the time of patient presentation at the clinic and recruitment) and the beginning of adaptive immune responses, respectively(4, 27). For the primary dengue patients, biomarkers associated with the functions of cytotoxic lymphocytes were enriched

84 in the serum of some patients in early acute infection (1-3 days post fever onset) (Figure 1A). Furthermore, 85 there were strong correlations between the levels of Granzyme A and IL-2, Granzyme B and IL-17, and IL-86 4 and TNF in patient sera (Figure 1A), which suggests clustering of patients whose early immune profiles were typified by Th1, Th17 or Th2 type responses. IL-10 and IFN- γ levels also appeared correlated with 87 88 each other (Figure 1A), which have previously been shown to be produced by CD4 T cells and linked to 89 dengue disease(28). We next guestioned whether the serum levels of any of these cytokines were 90 associated with the early induction of a Th1-polarized antibody response. Interestingly, the levels of 91 granzyme K during the acute phase of infection were significantly higher in patients who displayed effective 92 class-switch of DENV-specific antibodies to the Th1-associated isotype IgG3, which was measured in the 93 defervescence phase of disease in longitudinal samples (Figure 1B). DENV-specific IgG4, which is a Th2-94 associated human antibody subclass(29) could not be detected, which is consistent with literature 95 suggesting that it takes several weeks for IgG4 induction following primary DENV infection(30), while IgG2 96 was only detected in 14.3% of patients (Figure S1A). These IgG3 and IgG4 antibody subclasses are usually 97 low abundance in human serum compared to IgG1/2 and, aside from being associated with Th1/2 98 polarization, can illustrate a refined antibody response following germinal center activity and effective class-99 switching(31). In contrast, IgG1, the most abundant subclass of serum antibodies in humans(31), was 100 produced by 97% of patients by this time point post-fever onset but did not correlate with Granzyme K 101 (Figure S1B-C). In spite of its association with Th1-polarized IgG3 antibody responses, granzyme K was 102 not associated with serum virus burden or disease severity during primary infection (Figure S1D-E). 103 Granzyme K is produced primarily by NKT cells, although to a lesser extent by yoT cells, but not made 104 appreciably by traditional CTLs(32). Even though Granzyme K is not cell type-specific, its strong association 105 with NKT cells raised the question whether early NKT cell responses could influence the mounting adaptive 106 immune response and Th1 balance during DENV infection.

107

108 CD1d^{dep} NKT cell deficiency alters cellularity of DENV-infected skin and dLNs.

Prior to assessing the functional contributions of NKT cells to virus clearance and adaptive responses, we characterized the NKT cell response at the cutaneous site of DENV infection and the dLN, where immunity is initiated, in a well-established immune-competent mouse model of DENV infection(6, 11,

5

112 33-36). Since mosquitoes inject DENV particles subcutaneously during their feeding (37) and because the 113 mouse footpad (FP) skin drains to a single dLN, the popliteal lymph node (38), we chose this route of 114 infection to examine NKT cell responses. DENV is also a lymphotropic pathogen, and the dLN is the 115 secondary site of infection(4, 9). First, we infected WT and CD1d-KO mice with DENV2 (2x10⁵ PFU) via subcutaneous injection and determined the relative NKT cell sub-types present in the FP skin and dLN by 116 117 flow cytometry at days 3 and 5 post-infection (Figure 2A), which were defined based on cellular markers 118 identified in prior reports (13, 15, 39, 40). A CD1d-tetramer loaded with PBS-57, an analogue of a GAICer, 119 was used to identify Type-I NKT (iNKT) cells, while Type-II NKT cells that are also CD1d-restricted would 120 not bind to the αGAICer-loaded tetramer. An unbiased multidimensional reductional analysis (t-sne) was 121 used to visualize and verify the phenotypic differences in NKT cell populations between WT and CD1d-KO 122 mice in the skin and dLNs (Figure 2B). This confirmed the expected absence of Type-I NKT cells 123 (NK1.1⁺CD3⁺CD1d-tetramer⁺) in the skin and dLN (Figure 2B). In the FP skin of WT mice, we detected NKT-like cells (NK1.1⁺CD3⁺CD1d-tetramer⁻CD8⁺), with very small numbers of either Type-II NKT cells (or 124 125 CD4 T cells that had acquired the NK1.1 marker, which are phenotypically indistinguishable from NKT cells) (NK1.1⁺CD3⁺CD1d-tetramerCD4⁺), and CD4/CD8 double-negative (CD4/CD8 DN) NKT cells 126 (NK1.1⁺CD3⁺CD1d-tetramer CD4⁻CD8⁻) (Figure 2B). In WT mice, the CD4/CD8 DN NKT population 127 128 represents a combination of some Type-II NKT cells and NKT-like cells, although based on the CD1d-129 restriction of Type II NKT cells, the same phenotype should represent only NKT-like cells in CD1d-KO mice. As expected, CD1d-KO mice lacked Type-I and Type-II NKT cells (Figure 2B), and their small residual 130 131 NK1.1⁺CD4⁺ population should represent T cells that have acquired the NK1.1 marker, which can occur during viral infection (21), while their CD4/CD8 DN population of NK1.1+CD3+ cells should represent NKT-132 like cells only. Thus, CD1d^{ind} NKT-like cells were the dominant cell population with NKT cell markers in 133 134 CD1d-KO mice at baseline (Figure 2B).

After subcutaneous infection with DENV, total NKT cells were enumerated in the skin and dLNs. In contrast to NK cells, which did not differ between WT and CD1d-KO mice (**Figure S2A-B**), there were reduced NKT cells in the skin of CD1d-KO mice compared to WT mice, days 3 and 5 post-infection (**Figure 2C**). However, the total NKT cells did not differ in the dLN between WT and CD1d-KO mice at the same time points of this experiment (**Figure S2C**). In infected WT mice, we also detected a significant increase 140 in Type-I NKT cells in both the FPs and LNs on days 3 and 5 post-infection (Figure 2D-E). Furthermore, 141 significantly increased numbers of NKT-like cells were present on days 3 and 5 post-infection in the FPs 142 but not dLNs of WT mice but not in CD1d-KO mice (Figure 2F, S2D). This was confirmed by confocal 143 microscopy, where CD3⁺ or NK1.1⁺ single-positive cells could be identified in the infected skin of CD1d-KO 144 mice, but no double-positive NKT cells could be found, in contrast to WT skin where they were rare, but 145 present (Figure S2E). These results suggest that although NKT-like cells are present in CD1d-KO mice, their recruitment to DENV-infected skin is regulated by CD1d^{dep} NKT cells, which are absent in this model, 146 147 and they are not replenished in the skin following infection. To further validate defects in the recruitment of 148 immune cells to the site of cutaneous DENV infection in the absence of CD1d^{dep} NKT cells, we used 149 carboxyfluorescein succinimidyl ester (CFSE) labeling of cells in the FP skin prior to infection to label 150 resident cells (CFSE⁺). We observed significantly higher numbers of newly recruited, CFSE⁻ NKT-like cells 151 in the skin of WT mice compared to CD1d-KO mice on day 3 post-infection (Figure 2G). However, we did not detect a significant difference in the number of tissue-resident, CFSE* NKT-like cells in the skin of WT 152 and CD1d-KO mice (Figure 2G). Therefore, the increase in CD1d^{ind} NKT-like cells observed in the skin 153 154 during DENV infection was primarily due to newly-recruited cells. Together, these data demonstrate that CD1d^{dep} NKT cells are necessary for the trafficking of CD1d^{ind} NKT-like cells into the cutaneous site of 155 156 **DENV** infection.

157

158 In the dLN, NKT cell phenotypes were similarly analyzed, and we detected diverse subsets of NKT cells and an increase in CD1d^{ind}NKT cell subsets in both WT and CD1d-KO mice following DENV2 infection 159 (Figure S2D). In contrast to observations made in the skin, CD1d^{ind} NKT-like cells increased to comparable 160 161 numbers in the dLN of CD1d-KO mice compared with WT mice and the numbers of CD4/CD8 DN NKT cells 162 were also increased but not significantly different between WT and CD1d-KO mice (Figure S2D). We also 163 detected increased numbers of NK1.1⁺CD3⁺CD1d-tetramer⁻ cells in CD1d-KO mice, (Figure S2D), 164 which are likely CD4⁺ T cells that acquired the NK1.1 marker, as conventional CD4⁺ and CD8⁺ T cells have 165 been shown to express NK1.1 upon acute viral infection(21). Similarly, to the skin, NKT cells could be 166 identified visually in the infected LNs of WT mice, but these were not abundant in dLN of CD1d-KO mice 167 (Figure S2F-G). These results support that, unlike the skin site of infection where recruitment of CD1d^{ind} 168 NKT cell types was affected by CD1d-deficiency, the cellularity of the dLN with regards to NKT cell subsets
 169 was not significantly affected, aside from the confirmed lack of CD1d^{dep} NKT cells.

170 To further characterize the subsets of NKT cells in the LN following infection in WT and CD1d-KO 171 mice, we sorted NK1.1⁺CD3⁺ cells for TCR sequencing. The sequencing results, indicating an increase in TCR diversity in WT but not CD1d-KO mice upon infection, shown by diversity index and visually by tree 172 173 map presentation of the individual clones (Figure 3A-B), supported the interpretation that diverse NKT-like 174 cells were recruited in the presence of CD1d-restricted NKT cells. A more in-depth analysis of the V and J 175 pairs showed that certain clones were highly enriched in WT animals, such as pairings of mTRBV12-2 with 176 mTRBJ1-5 or mTRBJ1-4, in addition to the broad increase in frequencies of multiple diverse TCRβ clones 177 (Figure 3C). There were many clones that were only detected in the LN of WT mice during DENV infection, 178 and fewer that were only detected in infected CD1d-KO mice (Figure 3C). This might also be consistent 179 with the acquisition of NK1.1 as a marker on conventional T cells in CD1d-KO mice, although there were 180 only 3 clones that were uniquely identified in CD1d-KO mice upon infection (Figure 3C), suggesting the 181 potential of this to occur would be very limited. Together these data emphasize the role of CD1d^{dep} NKT 182 cells, which are invariant, in promoting NKT cells or NKT-like cells with diverse repertoires during infection.

183

184 CD1d^{dep} NKT cells enhance CTL recruitment and promote resolution of infection.

Next, to examine how CD1d^{dep} NKT cells affect virus clearance, we measured the infection burden 185 186 at the site of infection, the FP skin, and in the dLN of WT and CD1d-KO mice on days 3 and 5 post-DENV2 187 infection. Staining of dLNs for monocyte and DC markers CD11b and CD11c revealed that most of the 188 infected cells that were increased were myeloid lineage cells that are known DENV infection targets (Figure 4A). The differences in viral genome copies were not significantly different in the FP and dLN at day 3 post-189 190 infection between WT and CD1d-KO mice (Figure 4B-C). By day 5, higher DENV2 infection levels were 191 detected in the skin (Figure 4B) and dLNs (Figure 4C) of CD1d-KO mice compared to WT mice. This 192 increased burden in the dLN was confirmed day 5 by IHC (Figure S3). These results suggest that CD1d^{dep} 193 NKT cells promote the resolution of DENV infection and that their absence leads to delayed viral clearance. 194 To identify the aspects of cellular immunity that could mediate delayed viral clearance in the context of CD1d^{dep} NKT cell deficiency, we examined other conventional T cell responses associated with viral 195

196 clearance, including CD8⁺ CTLs. Indeed, delayed DENV2 clearance in the skin of CD1d-KO mice was 197 associated with a reduced CTL response, as there were fewer total and activated CD8⁺ T cells in the skin 198 of CD1d-KO mice at days 3 and 5 post-infection (Figure 4D). In contrast to skin, similar numbers of total 199 and activated CD8⁺ T cells were detected in the dLNs of WT and CD1d-KO mice (Figure 4E). We also 200 quantified tissue resident or newly recruited CD8⁺ T cells in the FP skin at day 3 post-infection to determine 201 whether the reduction in CTL numbers in CD1d-KO skin was due to impaired recruitment and/or in situ 202 proliferation of CD8⁺ T cells. We observed significantly higher numbers of both newly recruited CFSE⁻CD8⁺ 203 T cells and tissue-resident CFSE⁺CD8⁺ T cells in the FPs of WT mice compared to CD1d-KO mice day 3 204 post-infection, yet no changes at baseline (Figure 4F). These labeling experiments support that the 205 increase in CD8⁺ T cells in the skin during DENV infection is due to both new recruitment and in situ proliferation of CD8⁺ T cells and that CD1d^{dep} NKT cells are necessary for the trafficking of CD8⁺ CTLs 206 207 within DENV-infected skin and their expansion.

208 The higher viral load in the dLN of CD1d-KO mice despite the unaltered CTL response at that site 209 suggested other mechanisms leading to the amplification of DENV infection in the dLN might exist, aside 210 from merely impaired CTL-mediated clearance of infection. As DENV is lymphotropic and infection-bearing 211 DCs and inflammatory monocyte-derived cells migrate from the cutaneous infection site to the dLN for 212 systemic virus spread(9, 41), we hypothesized that reduced clearance of DENV in the skin may allow 213 enhanced trafficking of infected cells to the dLN in CD1d-KO mice. To investigate whether this occurred, 214 we injected CFSE into the FPs of WT and CD1d-KO mice 3 days after subcutaneous DENV2 infection and 215 tracked CFSE⁺ and CFSE⁻ monocyte/macrophages (CD11b⁺CD11c⁻MHC-II⁺, gating strategy Figure S4) and conventional DCs (cDCs, CD11c⁺CD11b⁻MHC-II⁺, gating strategy Figure S4) in the dLN at day 5 post-216 217 infection by flow cytometry. We detected significantly higher numbers of DENV-infected 218 monocyte/macrophages (Figure 4G) and cDCs (Figure 4H) in the dLNs of CD1d-KO mice by intracellular 219 staining for the DENV replication product NS3. We also observed significantly higher numbers of skin-220 derived (CFSE⁺) DENV-infected monocyte/macrophages (Figure 4G) and cDCs (Figure 4H) in the dLNs 221 of CD1dKO mice. These data indicate that the delayed viral clearance observed in the dLNs of CD1d-KO 222 mice (Figure 4B-C) coincides with increased migration of DENV-infected monocytes and DCs from the 223 infected skin, where viral clearance is also impaired.

224 Our data also indicated that the changes in trafficking within the skin were cell type-specific since 225 the responses of other T cells including yδT cells, which are important for early flavivirus clearance from 226 skin(11, 42), were unaffected in the skin due to CD1d deficiency (Figure S5A). While we observed a 227 significant reduction in total CD4⁺ (Figure 4I) and γδT cell (Figure 55B) numbers at days 3 and 5 post-228 infection in the dLNs of CD1d-KO mice, there were no differences in the numbers of activated CD4⁺ and 229 γδT cells between WT and CD1d-KO mice (Figure 4I, S5B). Taken together, these data demonstrate that 230 during DENV infection, CD1d^{dep} NKT cells influence T cell recruitment in the skin and dLN in a site-specific 231 manner by promoting CD8⁺ CTL recruitment and activation in the skin and expansion of CD4⁺ and γδT cell 232 populations in the dLN, without affecting their activation potential.

233

234 CD1d^{dep}/Type-I NKT cells establish Th1 polarity during DENV infection.

235 We hypothesized that the defects in CTL and NKT-like cell recruitment to the skin and the 236 enhanced trafficking of infected cells from the skin to the dLN in CD1d-KO mice could be due to altered 237 chemotactic gradients. Therefore, we compared the mRNA expression levels of various chemokines in the 238 FPs and dLNs of WT and CD1d-KO mice following subcutaneous DENV2 infection. At 48h post-infection, 239 significant reductions in the mRNA expression levels of Cxcl9 and Cxcl10 were detected in the FP skin of 240 CD1d-KO mice compared to WT mice (Figure 5A). These chemokines are well-established to be important 241 for the recruitment of Th1 cells and activated CD8⁺ T cells that express the chemokine receptor CXCR3(43). 242 Similarly, in the dLNs of CD1d-KO mice compared with WT mice, we detected a significant reduction in 243 mRNA expression levels for Cxcl16 (Figure 5B), a chemokine for CXCR6-expressing Th1 cells(44), but not Cxcl10. Consistent with increased infiltration of infected monocytes and DCs in the dLNs of CD1d-KO 244 245 mice (Figure 4G-H), significant increases in mRNA expression levels for Ccl7 and Ccl8 (Figure 5B) were 246 detected in the dLNs of CD1d-KO mice compared to WT mice. Ccl7 and Ccl8 are well-established 247 attractants for monocytes and DCs, as well as some cell types with Th2 phenotypes (43, 45-50). These 248 differences in the expression levels of various chemokines suggested a shift from a Th1 towards a Th2 bias 249 in CD1d-KO mice in both the skin and dLN.

To identify which subsets of NKT cells produce Th1-associated chemokines, we further examined chemokine expression by each NKT cell subset following DENV infection. For this, we sorted Type-I, -II,

10

252 and NKT-like cells from the dLNs of DENV2-infected WT mice at 48h post-infection and examined mRNA 253 expression levels in each NKT cell subset for Th1 and Th2 chemokines by real-time qPCR. The fold change 254 in chemokine expression levels in Types-I, -II, and NKT-like cells from DENV2-infected mice were 255 compared with the expression levels in total NKT cells from uninfected mice to indicate the relative 256 contributions of each subset to the cytokine profile observed. In the DENV-infected WT mice, we detected 257 ~18- and ~6-fold increases in Cxcl10 expression in Type-I and -II NKT cells relative to baseline, respectively, 258 while Cxcl10 expression by NKT-like cells increased ~23-fold (Figure 5C), indicating that NKT cells, 259 particularly Type-I and NKT-like subsets, are important producers of Cxcl10. Consistent with the increased 260 expression of Th1 chemokine Cxcl10, Ifng expression was also significantly increased in Type-I and NKT-261 like subsets (Figure 5C), supporting that Type-I NKT and NKT-like cells promote a Th1 response during 262 **DENV** infection.

263

264 CD1d^{dep} NKT cell deficiency results in Th1/Th2 imbalance

265 Since our chemokine expression data suggested Th2-skewing due to CD1d^{dep} NKT cell deficiency, 266 we next aimed to confirm this functionality at the protein level and determine whether CD4⁺ and CD8⁺ T 267 cells, which are key effectors of Th1/Th2 polarization, were also affected. For this, we compared the 268 frequency of IL-4- or IFN-γ-producing CD4⁺ and CD8⁺ T cells in the dLN of WT and CD1d-KO mice by 269 intracellular staining. Consistent with a shift towards Th2 polarization in the absence of CD1d^{dep} NKT cells, 270 significantly higher frequencies of IL-4-producing CD4⁺ T cells and lower frequencies of IFN-y⁺ CD4 T cells 271 were detected in the dLNs of CD1d-KO mice compared to WT mice (Figure 6A-B). In addition, we 272 compared the frequency of IL-4- or IFN-y-producing CD8⁺ T cells in the dLNs and observed higher 273 frequencies of IL-4-producing CD8⁺ T cells and lower frequencies of IFN- γ^+ CD8⁺ T cells in CD1d-KO mice compared WT mice (Figure 6C-D). Alternatively presented, a UMAP analysis allowed visualization of 274 275 affected CD4 and CD8 populations in infected LNs (Figure 6E), where a heat map presentation of IL-4 276 expression showed an increased density of IL-4 expressing cells in CD1d-KO mice compared to WT 277 controls, particularly identifiable in the CD4⁺ cell region (turquoise bracket, Figure 6F) while increased 278 intensity for IFN-γ expression was discernable in WT mice compared to CD1d-KO mice in the area of the 279 UMAP plot corresponding to CD8 T cells (pink bracket, Figure 6G). Assessment of IFN-γ and IL-4 MFI in

280 CD4 and CD8 T cells indicated that expression of IFN- γ was increased in both CD4 and CD8 compartments 281 in WT compared to CD1d-KO mice (**Figure 6H-I**), while the MFI of IL-4 did not differ significantly (**Figure** 282 **6J-K**), in spite of the expanded proportion of IL-4⁺ T cells in CD1d-KO compared to WT mice (**Figures 6A**). 283 These data demonstrate that during DENV infection, CD1d^{dep} NKT cells are required for the optimal 284 production of the Th1 cytokine IFN- γ by CD4⁺ and CD8⁺ T cells and that their absence causes a Th1/Th2 285 imbalance, resulting in an enhanced presence of CD4⁺ and CD8⁺ T cells producing the Th2 cytokine IL-4.

286 Having identified defects in Th1 immunity in CD1d-KO mice and the induction of Th1 cytokine IFN-287 γ by Type-I NKT and NKT-like cells in response to DENV infection (**Figures 5-6**), we hypothesized that IFN- γ production by NKT cells could initiate the Th1 microenvironment. To test this, we adoptively transferred 288 isolated NKT cells from either WT or IFN-y-KO mice into CD1d-KO recipients prior to DENV infection 289 (Figure 7A). At day 3 post-infection we observed increased infection in the LNs of mice that had been 290 transferred CD1d-KO NKT cells compared to WT NKT cells (Figure 7B). We then measured cytokine 291 292 production and cellular activation in the CD4 and CD8 T cell compartments of the skin and dLNs. NKT cell 293 transfer from IFN-γ-deficient into CD1d-KO mice resulted in a significant increase in CD4 T cell but not CD8 T cell IL-4 production in the dLN (Figure 7C, S6A) and decrease in CD4 and CD8 T cell IFN-y production 294 during DENV infection compared to transfer of NKT cells from WT mice (Figure 7D). Transfer of WT NKT 295 296 cells prior to DENV infection also promoted increased activation of CD4 and CD8 T cells in the dLNs 297 compared to transfer of IFN- γ -deficient NKT cells (**Figure 7E**). The influence of NKT cell derived IFN- γ on 298 Th1 polarization was also observed in the skin site of infection (Figure 7F-G). Consistent with the dLN, IL-299 4-producing CD4 and CD8 T were fewer (Figure 7F) and IFN- γ -producing T cells were increased (Figure 7G) in the DENV-infected skin of animals adoptively transferred WT NKT cells compared to IFN-γ deficient 300 301 NKT cells. The IFN-y-deficient NKT cell transfer also led to reduced recruitment of CD8 T cells in the skin during DENV infection, compared to transfer of WT NKT cells (Figure 7H), while the frequencies of NKT 302 303 cells in the skin did not differ between the two groups (Figure S6B). These data show the contribution of 304 IFN- γ produced specifically by NKT cells in promoting the Th1-type response. In the absence of IFN- γ in 305 NKT cells, IL-4 production by conventional T cells is enhanced.

306

307 NKT cells promote antibody production that protects against homologous and heterologous reinfection

308 Since the Th1/Th2 cytokine imbalance could directly influence humoral immunity(51) and based on 309 our observations linking antibody sub-classes and NKT cell biomarkers in humans (Figure 1), we further 310 examined how CD1d^{dep} NKT cell deficiency affects the Th1/Th2 balance in the antibody response against DENV. For this, we infected WT and CD1d-KO mice with DENV2 and determined DENV2-specific serum 311 312 IgG2a (Th1-associated) and IgG1 (Th2-associated)(51-53) antibody titers at 5 weeks post-infection. 313 Although total antibody titers against DENV determined by ELISA did not differ (Figure S7), we observed 314 significantly higher DENV-specific IgG2a titers in WT mice compared to CD1d-KO mice (Figure 8A), while 315 IgG1 titers were higher in CD1d-KO mice (Figure 8B). These changes indicate a strong Th1 antibody 316 response against DENV2 in WT mice and a Th2 skewing of the antibody response against DENV2 in CD1d-317 KO mice. Assessment of the neutralizing capacity of the purified IgG from WT and CD1d-KO mice also 318 indicated that IgG from CD1d-KO mice was unable to neutralize DENV2 efficiently (Figure 8C-D), supporting the role of CD1d^{dep} NKT cells on antibody function and raising the further question of how the 319 320 persistence of an Th2-skewed profile could influence subsequent immunity to DENV.

321 Given the differential protective responses during homologous and heterologous secondary 322 infections with dengue, we tested the influence of antibodies produced in WT or CD1d-KO mice with both 323 types of challenge. For this, we purified serum IgGs from naïve WT, DENV2-immune WT and DENV2-324 immune CD1d-KO mice, 28 days after infection prior to adoptive antibody transfer and challenge of 325 recipients (Figure 8E). Prior to transfer of antibodies, immune complexes were formed using either purified 326 IgGs and DENV2 (homologous challenge) or purified IgGs and of DENV1 (heterologous challenge). The 327 immune complexes were then injected into the skin of IFNaR/IFNyR-KO mice, which are highly susceptible 328 to DENV infection(54), and viral titers were measured in the dLN at 5 day post-infection. In the homologous 329 challenge model, IgGs from DENV2-immune WT mice provided protection against DENV2 infection 330 resulting in reduced viral titers compared to the IgGs from naïve or CD1d-KO infection groups (Figure 8F). 331 In contrast, with heterologous challenge, IgGs from DENV2-immune WT mice increased DENV1 infection, 332 consistent with ADE (Figure 8G). However, ADE of DENV1 was significantly enhanced in the presence of 333 IgGs from DENV2-immune CD1d-KO mice compared to IgGs from DENV2-immune WT mice (Figure 8G). 334 Next, we guestioned whether the ADE observed with IgG from CD1d-KO mice could worsen dengue

335 disease. Using the heterologous infection model described above we measured body mass and survival in 336 IFNaR/IFNyR-KO mice. DENV1 infection in mice who received IgG from DENV2-immune CD1d-KO mice 337 showed significantly more weight loss (Figure 8H) and higher mortality (Figure 8I) compared to the mice 338 who received IgG from DENV2 immune WT mice. These results were also consistent using 339 immunocompetent model of dengue infection where weight loss was increased in mice given CD1d-KO 340 immune complexes, although both groups recovered (Figure S8). This supports that a higher anti-DENV 341 IgG1/IgG2a ratio may promote the development of ADE upon subsequent heterotypic DENV infection. 342 Therefore, CD1d^{dep} NKT cell regulation of Th1 immune polarization during DENV infection not only 343 enhances cellular immunity and recruitment to assist with DENV infection clearance but also alters the long-344 term immune status towards a protective Th1 serological profile.

345

346 Association of pre-existing Th2-associated IgG4 with dengue severity in humans

347 Next, we evaluated if Th2-polarized antibody responses are associated with severe disease in humans. For this, we measured DENV-specific IgG1, IgG2, IgG3 and IgG4 in a cohort of secondary dengue patients. 348 349 Interestingly, patients who developed dengue fever (DF), the mild form of dengue disease, had higher levels of IgG3 (a Th1-associated antibody) and lower levels of IgG4 (a Th2-associated antibody) compared to 350 351 those who developed dengue hemorrhagic fever (DHF), a severe form of dengue (Figure 9A-C). Levels of 352 DENV-specific IgG1 did not differ between mild and severe patients, while IgG2a was only detected in a 353 small number of patients (Figure S9). Consistent with this, the ratio of IgG4/IgG3 was significantly higher 354 in DHF patients compared to DF patients (Figure 9D). This further supports our mechanistic data that Th2 355 skewed antibodies that are formed in the absence of NKT cell functionality are weakly neutralizing and may 356 promote antibody-enhanced disease severity.

357

358 Discussion

A first exposure to a viral pathogen is typified by infection clearance through cytotoxic T cell responses, including innate-like T cells(55). However, it has been unclear whether innate-like T cell functionality during a primary infection can influence disease outcomes during a secondary re-exposure. It is also unclear how innate-like T cells, such as NKT cells, could function to bridge innate and adaptive

14

immune responses in these contexts in ways independent of their own capacity to develop a memory phenotype. Here, we identified that NKT cells do not merely promote an acute antiviral response through cytotoxicity, but they also help guide the fate of the memory lymphocyte pool during a primary adaptive immune response, in ways that can be protective much later during reinfection.

367 By using mouse models of CD1d-deficiency, we showed that IFN- γ derived specifically from 368 CD1d^{dep} NKT cells during primary DENV infection was instrumental in defining infection outcomes during a 369 secondary DENV infection. In humans, a cytokine signature involving early induction of granzyme K in the 370 acute phase of primary dengue disease was strongly linked to induction of Th1-associated IgG3 as infection 371 resolved. Although granzyme K is not specific to NKT cells(32), given its importance to their function we 372 investigated the contributions of NKT cells in immune polarization and infection clearance in mice. 373 Mechanistically, CD1d^{dep} NKT cells established IFNγ-driven Th1 bias that extended to both T cell responses 374 as well as to antibody subclasses and their functionalities, which paralleled our observations in primary 375 dengue patients. In particular, DENV-specific antibodies evoked in the absence of CD1d^{dep} NKT cells were 376 poorly neutralizing in spite of having been generated in the presence of a higher infection burden. 377 Functionally, these antibodies were enhancing for viral replication during secondary heterologous DENV 378 infection and even failed to protect in a homologous DENV challenge. In humans with secondary dengue 379 infections, we also observed a correlation between the presence of DENV-specific Th2-associated antibody 380 subclasses and a high Th2:Th1 antibody ratio with severe dengue. However, we did not have sufficient 381 serum from this study to perform neutralization tests against all of the serotypes of DENV in circulation in 382 Sri Lanka, so we do not know if the neutralizing capacity of serum antibodies is also linked to severe disease 383 in this cohort. Interestingly, IgG3 antibodies have been characterized to have greater neutralizing capacity 384 in some contexts, such as against SARS-CoV-2 virus(56). Multiple DENV infections are likely in dengue 385 endemic regions and re-exposure to a heterologous dengue serotype is a known risk factor for developing 386 severe dengue(4). This emphasizes the potential that the innate immune activation profile an individual 387 mounts during primary infection can drive the responses that determine disease severity during secondary 388 infection, likely many years later.

389 NKT cells display plasticity in their phenotypes and can secrete Th1, Th2, or Th17 cytokines under
 390 different circumstances. Most literature examining the role of NKT cell polarization has focused on the

15

391 phenotypes of those cells during autoimmunity(57). Even the timing and circumstances of 392 αGalCer administration can lead to altered Th1/Th17 vs. Th2 bias(58). We observed in mice that Type-I 393 NKT cells and NKT-like cell subsets are the sources of IFN-y during acute dengue infection that initiate the 394 Th1 microenvironment to which other cells, like T cells, also contribute. TCR sequencing supported our 395 flow cytometry data showing that CD1d-dependent NKT cells expand the population of NKT-like cells at 396 infection sites and dLNs and promote their cytokine production as well, considering that the presence of 397 CD1d-dependent NKT cells lead to increased diversity of NKT-like cell clones. It would be interesting, in 398 future studies to identify the infection-associated products that these diverse NKT cell clones recognize.

399 Evidence supports that IFN-y is protective during dengue. For example, in one cohort, sustained 400 IFN-y production correlated with protection against fever and viremia (59). Furthermore, IFN-y mediates 401 nitric oxide production and reduces DENV replication and disease severity in mice (60, 61). Despite these 402 and additional numerous examples of the innate protective functions of IFN- γ (62), the influence of IFN- γ on 403 antibody quality during viral infections not straightforward. On the one hand, IFN-y is produced abundantly 404 by conventional $\alpha\beta$ T cells(63) and it can promote T helper cell function(64) and B cell activation and 405 proliferation(65). Also, IFN-y has been shown to promote germinal center functions, particularly in the 406 context of autoimmunity(66, 67). However, in some models of viral infections, IFN-y is dispensable to 407 antibody production or antibody-mediated protection from heterotypic strains(68, 69). We also previously 408 observed that IFN-y-receptor-deficient mice have severely compromised survival compared to IFN-y-409 receptor-sufficient littermates, in a model of maternal antibody-mediated severe DENV infection (that is also 410 Type-I interferon deficient)(70). In contrast to those systems, we see here that IFN-y from NKT cells is 411 protective during primary and secondary DENV infection. Transfer of NKT cells from WT mice but not IFN-412 y-KO mice resulted in the restoration of a Th1-polarized immune response at the site of infection in the skin 413 as well as dLNs, emphasizing the mechanistic importance of NKT cell derived IFN-y in establishing the 414 polarization of the immune microenvironment, a role that might not have been apparent in systems with 415 global deficiency or antibody-blockade. Importantly, since IFN-γ-competent NKT cells from WT mice were 416 sufficient to repair a Th1-polarized response, even in CD1d-KO mice, this supports that the contributions 417 of CD1d^{dep} NKT cells to Th1 polarization are independent of the ability of the host to present antigen via 418 CD1d itself. This contrasts previously described influences of NKT cells on B cell responses, which were CD1d-dependent(71), or in other models of primary viral infection, IL-4-dependent(72). These observations also demonstrate the pleiotropic nature of IFN-γ and emphasize that IFNs derived from different cellular sources or from different time points during the course of infection have unique potential to dictate disease outcomes. These outcomes also may be distinctive in hosts experiencing multiple pathogen exposures. Although humans with DENV infection have activated circulating NKT cells(73), we cannot be sure that the same functional effects of Type-I NKT cells we defined in mice translate directly to humans, particularly given that humans have substantially fewer NKT cells in the blood than mice(74, 75).

426 Th1/Th2 bias also influences lymphocyte trafficking, which appears to contribute to viral clearance 427 during acute primary infection in our model. In CD1d-KO mice, chemokines important for cytotoxic cell 428 recruitment were reduced (such as CXCL9 and CXCL10 in the FP) in addition to the broad Th1 to Th2 429 shifted chemokine response in both the skin and dLNs. Consistent with this, CD1d-KO mice had defects in 430 the trafficking, proliferation, and activation of NKT-like cells and CD8⁺ CTLs into the cutaneous infection 431 site. CFSE tracking experiments also suggested increased trafficking of infected cells from skin to the dLN 432 and imaging revealed greatly enhanced numbers of infected myeloid lineage cells, which are known DENV-433 infection targets(4). Tracking of DENV-infected skin-derived monocyte/macrophage phenotype cells and 434 DCs post-infection showed that many of the infected cells in the dLN were derived from the footpad skin. 435 Importantly, in addition to an overall higher burden of infection, CD1d-KO mice also had increased numbers 436 of skin-derived infected cells in the dLNs compared to WT mice. This could point to impaired clearance by 437 cytotoxic cells of the infected cells in the skin that (by nature of being primarily antigen presenting cells) 438 migrate to the dLN. Yet, it is also likely that trafficking of infected cells was enhanced by the altered 439 chemotactic response. Particularly in dLNs, enhanced production of Ccl8 and Ccl7 was observed in CD1d-440 KO mice compared to WT mice, which, being monocyte and DC chemoattractants(47), could enhance the 441 trafficking of those cells both infected already or as potential infection targets. Thus, impaired trafficking of 442 cytotoxic cells is coupled with enhanced trafficking of infected cells and infection targets to the dLN in the 443 context of CD1d deficiency. This data provides greater context for the multiple roles of NKT cells during 444 infection. In addition to promoting innate and adaptive antiviral responses, as discussed above, they can 445 also regulate the cellular trafficking dynamics of immune cells responsible for infection clearance and/or 446 viral dissemination.

447 Previously, the influence of NKT cells on DENV infection and immunity had not been determined. 448 especially as it pertains to uncoupling of its cytotoxic function with that of its influence on immune polarity 449 and antibody functions. Dengue patients with severe disease were observed to have higher levels of 450 invariant NKT cell activation than mild patients (76), but this was studied only in secondary dengue patients 451 and whether increased NKT cell numbers resulted from activation during severe disease or was the cause 452 of severe disease is unclear. Interestingly, that study also observed that cytokines were produced by 453 invariant NKT cells with a higher IFN-v/IL-4 ratio in patients with mild dengue fever compared with those 454 with severe dengue fever(76). This is consistent with our results that Th1-associated NKT cell responses 455 are protective. Beyond DENV, many human viral pathogens have evolved into antigenically similar, but 456 evolutionarily divergent, families of viruses that confound or evade host defenses, for example, Influenza 457 viruses and Coronaviruses(77, 78). In those contexts, insufficient protection can result in antibody-458 dependent enhancement of disease or breakthrough infections caused by heterotypic strains. Improved 459 vaccination strategies to achieve strong cross-protective immune protection to subsequent challenges are 460 needed. Our results affirm that the contributions of NKT cells to protection from viral infection extends 461 beyond their innate functions to having a role in establishing a polarized and specific immune memory 462 response. This may have applications for improving vaccines to allow our immune systems to respond more 463 efficiently to heterologous sequential viral challenges.

464

465 Methods

466 Animal studies and infections

467 CD1d-KO, IFNαR/IFNγR-KO, and IFNγ-KO mice were purchased from Jackson Laboratories and bred in-468 house at the Duke-NUS vivarium. Wildtype mice (C57BL/6 background) were purchased from InVivos 469 (Singapore). DENV2 infection was performed by FP injection of 2×10^5 PFU or intraperitoneal injection of 470 1×10^6 PFU of DENV2.

471

472 Sex as a biological variable

473 For human studies, data are derived from both male and females. For mouse studies, mostly female mice474 were used and it is not known if the mouse model results pertain to male mice.

475

476 Statistics

For comparisons of multiple groups, either 1-way or 2-way ANOVA was performed using Bonferroni's multiple comparison post-test to determine statistical significance amongst groups. Unpaired Student's ttest was used to evaluate differences between two groups. Data were considered significant at $p \le 0.05$. All error bars represent the SEM. Multiplex cytokine data were analysed using data analysis software suite from Biolegend.

482

483 Study approvals

All animal experiments were performed according to protocols approved by the SingHealth Institutional Animal Care and Use Committee. IRB approvals were obtained from the University of Colombo, Colombo, Sri Lanka (#EC-14-136), the National University of Singapore, Singapore (#LN-18-036E) and Nanyang Technological University, Singapore (#IRB-2014-06-016). Subjects' guardians provided written informed consent prior to participation in the study.

489

490 Data Availability

491 Data are available in the "Supporting data values" XLS file; or from the corresponding authors upon request.

492

493 Supplementary methods accompany this manuscript.

494

495 Author Contributions

This study was conceived by ALS and APSR with experimental design and data interpretation by ALS, APSR, YC, and WAAS. The human biomarkers study was planned by AWS, MS, and ALS, with MS overseeing patient recruitment. Experiments were conducted and data acquired by YC, WAAS, AO, and APSR. Data were analyzed by YC, WAAS, APSR and ALS. The manuscript was written by ALS, APSR, WAAS and YC.

Figure 1

Figure 1. Association of serum Granzyme K concentrations with subsequent IgG3 induction in primary dengue patients. Concentrations of cytokines and T cell associated immune factors were determined in the serum of pediatric primary dengue patients (n=29). (A) Correlation matrix showing the correlation between concentrations of cytokines in patient samples at the acute (days 1-3 post-fever onset) phase of disease. Heatmap represents the correlation coefficients for each pair of cytokines evaluated. (Stronger positive correlations approach 1.) (B) Serum concentrations of Granzyme K were significantly higher in serum samples obtained 1-3 days post-fever onset for patients who had detectable anti-DENV IgG3 by days 6-7 post-fever onset. *indicates p=0.0495 determined by Mann Whitney test. IgG3 positivity was defined as having an anti-DENV endpoint ELISA titer 2-fold or greater above naïve serum.

Figure 2

Figure 2. Type I NKT and NKT-like cells are recruited to DENV-infected skin and dLNs. (**A**) Various NKT cell subsets from the skin and dLN were identified by flow cytometry using CD1d tetramer staining and additional markers, including Type-I NKT (NK1.1⁺CD3⁺CD1d-tetramer⁺), Type-II NKT cells (NK1.1⁺CD3⁺CD1d-tetramer⁻CD4⁺ which have a similar phenotype to NK1.1⁺CD4⁺ T cells), NKT-like NKT cells (NK1.1⁺CD3⁺CD1d-tetramer⁻CD4⁺), and CD1d-tetramer⁻CD4 CD8 double-negative (DN) NKT cells (NK1.1⁺CD3⁺CD1d-tetramer⁻CD4⁻CD8⁻). (**B**) The unbiased clustering tSNE algorithm was used to verify flow cytometry data in the FP skin and dLN. The algorithm was run on concatenated total samples (infected and uninfected). Type-I NKT cells were absent in CD1d-KO mice. (**C**) Total NKT cells were quantified in the

skin in WT and CD1d-KO mice after infection with 2x10⁵ PFU of DENV2 subcutaneously by FP injection. DENV infection increased Type-I NKT cells in WT but not in CD1d-KO mice in the (**D**) skin and (**E**) dLN days 3 and 5 post-infection. (**F**) Quantification of CD1d^{ind} NKT cell subsets in the FP showed increased NKT-like cells at days 3 and 5 post-infection in WT but not CD1d-KO mice, while other NKT cell subsets measured were not influenced. (**G**) Tracking of local versus recruited NKT-like cells in the skin, performed by CFSE labeling prior to DENV2 infection. CFSE⁺ or CFSE⁻ NKT-like cell (NK1.1⁺CD3⁺CD1d-tetramer CD8⁺) numbers in the FP skin were determined day 3 post-infection and are presented as stacked bars. Type-I NKT and NKT-like cells are recruited into the skin during DENV infection, and both subsets are absent from the skin of CD1d-KO mice. Graphed data are shown as the mean±SEM and consist of n=5 mice combined from two independent experiments for each time point; * for p<0.05, ** for p<0.01, and *** for p<0.001, determined by one or two-way ANOVA with Holm-Sidak's post-test.

Figure 3. Reduced diversity of NKT cell TCR clones in LNs of DENV-infected CD1d-KO mice. $CD3^+NK1.1^+T$ cells from mouse dLNs (mesenteric and iliac) collected and pooled from n=3 mice per group were harvested and sorted 72h hours after I.P. infection with DENV. The TCR β region was sequenced to identify the abundance of unique clones. (A) Diversity index calculated by iRepertoire software, which reflects the diversity of unique CDR3s clones sequenced for each sample. (B) Tree map illustration of diversity for the respective samples. (C) Heat map of the relative frequencies of given V-gene and J-gene combinations. The clones uniquely identified in WT or CD1d-KO mice are overlaid in pink and blue, respectively.

Figure 4

Figure 4. CD1d^{dep} NKT cells accelerate DENV clearance and promote CD8 T cell recruitment and activation in DENV-infected skin. WT and CD1d-KO mice were infected with $2x10^5$ PFU of DENV2 subcutaneously by FP injection. (A) DENV NS3 staining of infected cells including DCs and monocyte/macrophages at day 3 in the dLN of WT and CD1d-KO mice. Scale bar=50µM. Additional images are provided in Figure S2. (B-C) DENV2 (E protein) gene copy numbers in the (B) FP skin and (C) dLN were determined days 3 and 5 post-infection by qPCR. Single cell suspensions from FPs and dLNs were stained with antibodies against CD3, CD4, CD8, $\gamma\delta$ TCR, and CD69 for characterization of the T cell response by flow cytometry. Total and activated CD8⁺ CTL populations in the (D) FP skin and (E) dLN were determined days 0, 3, and 5 post-infection. Tracking of local versus recruited cells was performed by CFSE labeling prior to DENV2 infection. (F) CFSE⁺ (red) or CFSE⁻ (grey) CD8⁺ T cell (NK1.1⁻CD3⁺CD8⁺)

populations in the FPs were determined day 3 post-infection. To track infected cell migration, CFSE was injected into the FPs of WT and CD1d-KO mice 3 days after DENV2 infection. (G) DENV2-infected monocytes (CD45⁺CD11b⁺CD11c⁻MHCII⁺DENV-NS3⁺CFSE⁻, gray) and FP-derived, DENV2-infected monocyte/macrophage (CD45⁺CD11b⁺CD11c⁻MHCII⁺DENV-NS3⁺CFSE⁺; orange) numbers in the dLN were determined 5d post-infection. (H) DENV2-infected DCs (CD45⁺CD11b⁻CD11c⁺MHCII⁺DENV-NS3⁺CFSE⁺; gray) and FP-derived, DENV2-infected DCs (CD45⁺CD11b⁻CD11c⁺MHCII⁺DENV-NS3⁺CFSE⁺; purple) in dLNs were enumerated 5d post-infection. (I) Total and activated CD4⁺ T cells in dLNs were determined days 0, 3, and 5 post-infection. For all panels, n=6 mice for each time point. Data are shown as the mean±SEM. n.s.=not significant *p<0.05, **p<0.01, and ***p<0.001 by 2-way ANOVA with Tukey's posttest. For D-I, stacked bars are presented of CFSE⁺ and CSFE⁻ populations. CD1d-dependent NKT cells promote activation of CD8 T cells in DENV-infected skin and clearance of DENV from skin and dLNs.

Figure 5

Figure 5: CD1d^{dep} **NKT cells promote the expression of Th1-associated cytokines and chemokines in DENV-infected skin.** mRNA expression levels for various Th1- and Th2-chemokines in the (**A**) FP and (**B**) dLN of WT and CD1d-KO mice were compared 48h following subcutaneous DENV2 infection, quantified by real-time PCR (n=3 biological replicates). For **A-B**, data are shown as the mean ± SEM and presented relative WT uninfected controls. Dots represent technical replicates. *p<0.05 between WT and CD1d-KO mice determined by 2-way ANOVA with Bonferroni's posttest. (**C**) mRNA expression levels for cytokines/chemokines were determined by real-time PCR for individual NKT cell subsets, which were sorted from dLNs harvested from naïve WT mice or DENV2-infected WT mice at 48h post-infection (for each genotype, n=15 dLNs were pooled before sorting). The results are the average of triplicates, showing gene

expression in Types-I, -II, or NKT-like cells isolated from uninfected or DENV2-infected WT mice relative to expression in total NKT cells isolated from uninfected WT mice. Cytokine and chemokine responses are characteristic of a Th1 environment during DENV infection.

Figure 6: CD1d^{dep} **NKT cells promote Th1-associated cellular immunity.** The frequency of IL-4- or IFNγproducing CD4⁺ and CD8⁺ T cells in the LNs of WT and CD1d-KO mice was determined by intracellular staining, 3 days after subcutaneous DENV2 infection (n=4). Percentages of (**A**) IL-4-producing CD4⁺ T cells (NK1.1⁻CD3⁺CD4⁺IL-4⁺), (**B**) IFNγ-producing CD4⁺ T cells (NK1.1⁻CD3⁺CD4⁺IFNγ⁺) (**C**) IL-4-producing CD8⁺ T cells (NK1.1⁻CD3⁺CD8⁺IL-4⁺), and (**D**) IFNγ-producing CD8⁺ T cells (NK1.1⁻CD3⁺CD8⁺ IFNγ⁺) are shown. (**E**) UMAP analysis showing CD4 and CD8 populations in infected dLNs. (**F**) A heat map presentation of increased density of IL-4 expressing cells in CD1d-KO mice compared to WT, in the CD4 compartment. Blue bracket indicates region of interest with increased density of IL-4^{hi} cells. (**G**) Conversely,

increased intensity for IFN- γ expression in WT mice compared to CD1d-KO mice in the CD8 compartment. Pink bracket indicates region of interest with IFN- γ^{hi} cells (**H-I**) MFI of IFN- γ in CD4 and CD8 T cells indicated increased expression of IFN- γ in both CD4 and CD8 compartments in WT but not CD1d-KO mice. (**J-K**) MFI of IL-4 did not differ in either cell types. N=4 mice for each group and error bars represent mean±SEM. n.s.=not significant *p<0.05, **p<0.01, and ***p<0.001, determined by Student's unpaired t-test. During DENV infection, CD1d^{dep} NKT cells are required for the optimal production of the Th1 cytokine IFN- γ by CD4 and CD8 T cells and their absence causes a Th1/Th2 imbalance.

Figure 7: Th1 polarization is dependent on IFN-y production by NKT cells. (**A**) A schematic for the NKT cell transfer experiment showing purification of NKT cells from WT or IFN- γ -KO mice, and adoptive transfer 1 day prior to DENV2 infection in CD1d-KO mice. (**B**) DENV genome copies in dLNs day 3 post-infection. FP skin and dLNs were collected for intracellular staining of IL-4 and IFN- γ at 3 days post-infection. Frequencies of (**C**) IL-4 producing CD4 and (**D**) IFN- γ producing CD4 and CD8 T cells in the dLN after infection. Frequencies of activated CD4 and CD8 T cells in the dLN after infection. Frequencies of activated CD4 and CD8 T cells in the fP skin after infection. Frequencies of (**F**) IL-4 and (**G**) IFN- γ producing CD4 and CD8 T cells in the FP skin after infection. (**H**) Frequencies of total CD8 in the FP skin after infection. N=7-8 mice per group. *p<0.05, **p<0.01, ***p<0.001, and ***p<0.0001. For all panels, Student's unpaired t-tests were used, including for D-G, where CD4 or CD8 T cells were compared between groups. IFN- γ produced by NKT cells is required for optimal Th1-immunity.

Figure 8

Figure 8: CD1d^{dep} NKT cells promote Th1-associated humoral immunity that protects during homologous and heterologous reinfections. Comparison of serum (A) IgG2a and (B) IgG1 titers between WT and CD1d-KO mice. 3 weeks following DENV2 infection, determined by ELISA. WT and CD1d-KO mice received 1x10⁶ PFU of DENV2 via intraperitoneal injection. Endpoint titers were compared by Student's unpaired t-test, with *p<0.05 and ***p<0.001. (C-D) Plaque reduction neutralization test was performed using multiple equivalent concentrations of IgG purified from the serum of WT and CD1d-KO mice. Representative images are shown in D. (E) Schematic diagram of IgG purification from DENV2immune WT or CD1d-KO mice, followed by immune complex formation with either DENV1 or DENV2, and injection into recipient IFN α R/IFN γ R-KO mice. (F) Mice were infected with 1x10⁵ PFU of DENV2 or immune complexes formed from 1x10⁵ PFU of DENV2 and 1ug of IgG purified from DENV2 post-immune serum from either WT or CD1d-KO mice (homologous challenge). (G) Mice were infected with 2x10⁵ PFU of DENV1 or immune complexes formed from 2x10⁵ PFU of DENV1 and 10µg of purified IgG from DENV2 post-immune serum from either WT or CD1d-KO (heterologous challenge). For F-G, DENV virus burden was detected by PCR 5 days post-infection. Data are shown as the mean ± SEM. n.s.=not significant *p<0.05, **p<0.01, and ***p<0.001 by 1-way ANOVA with Holm-Sidak's posttest. (H) Weight loss was significantly more severe in IFNαR/IFNγR-KO transferred antibodies from CD1d-KO DENV2-immune mice compared to those transferred antibodies from WT DENV2-immune mice following DENV1 challenge. Because of missing data resulting from lack of survival, curves were compared by restricted maximum

likelihood (REML) mixed effects model and p<0.0001. (I) Survival also differed significantly in IFN α R/IFN γ R-KO mice by Log-Rank test. For **A-C** and **G-I**, N=5 per group. For **H**, N=4-5 per group.

Figure 9

Figure 9: Positive association between IgG4 induction and dengue severity in humans. (A) A heat map representing the DENV-specific IgG3 and IgG4 levels in pediatric dengue patients with secondary DENV infections. Patients diagnosed with DHF are indicated by an X to the right of the heat map. (B) IgG4 and (C) IgG3 endpoint titers in the serum of secondary dengue patients that were diagnosed with DF or DHF, measured in the serum isolated days 6-7 post fever onset. (D) Ratio of DENV-specific IgG4 to IgG3. For panels B-D, Endpoint values were compared between groups by Student's unpaired *t*-test. **** indicates p<0.001. For all panels, N=26 (DF) and N=22 (DHF) patients.
